THURSDAY, MAY 7, 1896.

SCIENTIFIC WORTHIES.

XXIX.—SIR JOSEPH LISTER.

I HAVE responded with great pleasure to the honourable request that I should give some sketch, for the readers of NATURE, of Sir Joseph Lister's scientific eminence. As a *confrère* I know him not merely from his prominent scientific renown, but also as a friend, and I too, like other German surgeons, have sought out the founder of modern surgery in his London hospital and, filled with gratitude, have laid my homage at his feet. Lister was many years ago in Leipzig, and I shall never forget the *fête* we then organised in his honour. How we cheered him on that evening, professors and students, old and young! For was it not in Germany first, rather than in England, that his scientific works met with their earliest recognition and general appreciation! Lister was in his day a prophet, and proclaimed a new doctrine for the healing of wounds. And how often prophets fail to find in their own fatherland, especially in the early stages of their activity, the recognition they so well deserve!

Lister's immortal life-work is his antiseptic method of operating and of treating wounds, and it constitutes the greatest advance which surgery has ever made. It is true that operational technique had reached a previously undreamt of development after chloroform and ether had banished pain in 1846 and 1847. But the surgery of those days wanted one thing more—certainty of a successful issue to its operations. Surgeons were still helpless in fighting the ever-present septicæmic infection of wounds, which snatched to the grave so many patients and injured sufferers. Were they but able to circumvent this deadly infection of the bodily fluids, the blood and the lymph, and could they but secure as a rule and not the exception the reactionless healing of wounds without inflammation and suppuration, then would surgery as an art be diverted into new channels, and strive for the goal of final perfection. It was exactly Lister's antiseptic method of operating and treating wounds which first showed the way to the attainment of that healing "by first intention," which had been a subject of discussion for centuries, and of that certain avoidance of traumatic infection of which the general nature was so well known. And now every day we note, with joyful and grateful hearts, and with hitherto unknown feelings of innermost satisfaction, the splendid outcome of this the greatest acquisition of modern surgery. Lister did not create antiseptic surgery suddenly, or without means to his hand, for the path was already smoothed with invaluable scientific facts from the domains of physiology, chemistry, botany, and general experimental pathology. Schulze, Schwann, Helmholtz, Schroeder, Dusch, and, above all, Pasteur had proved that all fermentations and putrefactions are due to organised germs, to those ever-present micro-organisms the schizomycetes or bacteria. This fact had at first received only scant attention, but in Lister's hands its importance for the development of surgery was immense. He began his experiments on the treatment of wounds in the Glasgow Infirmary, somewhere about the year 1864, and characterised his method as "antiseptic," since it was consciously and confidently aimed at the avoidance of all putrefactive changes in the parts affected. In his views as to the nature of traumatic infection, Lister took his stand on the basis of those scientific facts regarding fermentation and putrefaction which, as already stated, had been thoroughly established. He said to himself, "It is not the mere air as such that is antagonistic to the process of healing a wound, but rather those organised germs which are so universally disseminated in the world around us: bacteria are the cause of all inflammation and suppuration, and hence of septicæmia." In this persuasion he directly attacked the problem of how not only to exclude bacteria from entering a wound, but also to destroy by disinfectants those already present, and to stay their further development. Lister selected carbolic acid as a disinfectant. Now it is true that even before his time various antiseptics, and among these carbolic acid, had been employed in bandaging; but to Lister alone is due the unending merit of methodically and confidently working out the detailed technique of antiseptic operating

and bandaging. Like many a new invention, Lister's was also at first incomplete, and was attacked from many sides, partly as to the principles on which it was based, and partly on the grounds of the somewhat complicated manipulations it involved. But, firmly persuaded of the correctness of his theoretical views, he went on steadily developing the details of his antiseptic methods, at first in Glasgow, and later in Edinburgh and London. He endeavoured to prevent the entrance of bacteria by careful disinfection of every object which comes into direct or indirect contact with the wound, more especially of the operational area on the patient, of the hands of the surgeon and his assistants, of the instruments, sponges and absorbents. To the same end he introduced the use of carbolic "spray" during the operation itself and each subsequent change of dressings, and by his ingeniously devised carbolised gauze protected the wounds from further infection. Injuries or wounds already infected were methodically disinfected by 2·5 to 5·0 per cent. solution of carbolic acid. Lister's typical dressing, as it first came into more general use, was applied as follows. A layer of waterproof silk, the "protective," was placed over the wound to shield it from the direct action of the irritant substances (carbolic acid, paraffin) in the antiseptic dressing materials; over this came some eight or more layers of carbolised gauze or muslin, and between the outer two of these a sheet of gutta-percha tissue. The whole was then securely bound round with carbolised gauze so as to effect as far as possible an air-tight enclosure of the wound. This Listerian bandage, as it soon came to be called, was both applied and changed under a continuous carbolic spray.

The results which followed the application of Lister's methods, as used not only for operational but accidental injuries, were at that time—1873 to 1875—simply astounding. We read with the deepest satisfaction the surgical reports of those early days of the more general employment of Lister's antiseptic devices, and find them inspired with proud feelings as of a mighty victory finally won after prolonged and grievous defeats. No such curative results had ever been attained up to that time. In the self-same hospitals in which till then septicæmic infection had kept the upper hand, the best results were henceforth obtained, and the once-dreaded wound-fevers became more and more a rarity. Operations were now successful which had previously been nearly always fatal. The ever-advancing scientific investigations of traumatic septicæmia, more particularly as carried on by Koch and his pupils, and dealing with its origin and nature from the point of view of the deleterious action of bacteria, gave more and more a sound scientific basis for Lister's antiseptic method and removed all doubts as to the correctness of his views. Most convincing proof of the part played by the bacteria was provided by the inoculation of animals with pure cultures of these various organisms; and it was exactly and solely these experiments that proved the all-important fact that in reality all the troubles and dangers which threaten a wound, and hence the life of a patient, are determined by the deadly action of bacteria. This is the fact on which modern surgical methods are based. And in the face of this, people are still found who contest the utility of experiments on animals! It would be well if the opponents of vivisection could correctly picture to themselves the blessings for which the human race has to thank Lister's antiseptic method, and their relation to animal experiment. Did they but realise how many human lives are now saved in comparison with the past, surely they would be compelled to admit the use of vivisection. And, in the future also, scientific medicine imperatively demands experiments on animals for its investigations in the interest of mankind.

When once surgeons had learnt complete mastery of Listerian method, the results they obtained were progressively better. With the help of antiseptic precautions they succeeded in operations on which they would previously have never dared to venture. With these splendid results before their eyes, even those scattered opponents of the system who had at its inception raised their voice against it became silent, for they could no longer blind themselves to the conviction that a new and brilliant era was opening up for surgery.

After Lister's antiseptic method had become the common property of all surgeons, it was progressively improved and simplified, more especially in Germany. One of the most important facts for its further development was the proof that wound infections are chiefly due solely to actual contact with already infected objects, and that any infection by the entry of microbes from the neighbouring air rarely, if ever, occurs. Moreover, it was shown with increasing certainty of proof that under normal conditions the blood, lymph and tissues of healthy animals are free from bacteria. Upon these important facts the conclusion was based that it is unnecessary to disinfect a fresh and uninfected wound, such as a surgical incision, so long as every object which comes into direct or indirect contact with the wound is truly and perfectly sterilised or aseptic in accordance with Listerian requirements. Hence nowadays operations are performed with almost painfully precise sterilisation of every object or instrument employed, as Lister first taught us to do, while at the same time we limit as far as possible the action of irritant antiseptics, such as carbolic acid, and even advantageously use none at all, operating with as little fluid as possible. So far as it may be necessary the fluid now employed is a sterilised solution of common salt, or else sterilised water. In the place, then, of carrying out our operations under the former strictly antiseptic precautions, we now operate aseptically. But the fundamental idea on which Lister's antiseptic method was based has remained unchanged, and will always be the same. We deal with it in internal operations merely in a slightly different way, in so far as we omit the disinfection of wounds with such substances as carbolic acid or corrosive sublimate, regarding their action as unnecessary or even injurious. But all our precautions against traumatic infection are taken with the most minute care. The operational area on the patient is carefully disinfected in accordance with Lister's instructions, and is surrounded with aseptic linen compresses sterilised in steam at 100°–130° C. We employ exact and definite methods to free our hands from microbes, and the instruments are sterilised by boiling in 1 per cent. solution of sodium carbonate. All bandages and the outer garments we wear are made aseptic by prolonged exposure to steam at 100°–130° C. in a specially

constructed apparatus; and so, also, in respect of all else. Steam thus provides us nowadays with non-irritant bandaging materials free from germs with even greater certainty than did their earlier impregnation with antiseptic substances, for bacteria may always be found after the lapse of time in dry bandages which have been dipped in either carbolic acid or corrosive sublimate. Instead of sponges we now use muslin absorbents sterilised by steam, and these, like every other fragment of bandaging material, are burnt after being used but once. In short, the technique of modern surgery is based on Lister's method, and takes for its watchword "asepsis without the use of antiseptics." Antisepsis has given place to asepsis, but the latter is just as surely based on the ground first broken by Lister.

The results of operations carried out under aseptic precautions are magnificent. Surgery now celebrates its greatest triumphs in dealing with the skull and cranial cavity, with the brain, spinal column and spinal canal, with the thoracic and abdominal viscera, with bones and joints, with tendons and nerves. For accidental injuries, or wounds which are already infected, the older antiseptics are still employed, although we know that the complete disinfection of a festering wound is most difficult, nay almost impossible, for we cannot sufficiently reach the microbes lurking in the substance of the tissues. What we chiefly look to in this case is the efficient removal of the purulent secretion from the wound, securing this by free incisions and drainage.

Sir Joseph Lister must indeed experience a glorious feeling of deepest satisfaction when he surveys the labours of his life. His work is accomplished and brought to an incomparable conclusion. He has conquered and attained his object. When we but compare the surgery of thirty years ago, before Lister appeared on the scene, with that of to-day, what a change we see! We can scarcely carry ourselves back in imagination to the pre-antiseptic days of surgery, but each one who has known the older state of things from personal experience, cannot fail to realise with fuller understanding and livelier joy how great a blessing Lister is to suffering humanity. Formerly the healing of injuries or wounds after an operation lay by no means certainly in the hands of the surgeon. In many hospitals the conditions which existed before the advent of Lister were simply incredible. Innumerable victims were snatched away to death by traumatic infections. And how do things stand now? To-day, thanks to Lister, we can heal the most grievous injuries and carry out the most difficult operations without inflammation, suppuration, or fever. We have now a firmly grounded confidence in our surgical art, and our patients, too, trust to the capabilities of modern surgery, for they know that we can heal the wounds we make. The possibility now afforded by Listerian method of preserving and giving back health and life to our patients has led to the growth among the surgeons of every nation of a pride in their professional activities, which finds its expression in the form of active theoretical and practical work. Science and art are international. The doctors of all nations are fighting shoulder to shoulder for the welfare of suffering humanity, and we Germans recognise without a suspicion of jealousy that the sun of modern surgery first rose in the person of Sir Joseph Lister and in England. The word surgery in its origin signifies a handicraft; but that which was thus manual at first has become an art and a science which has, thanks above all to Lister, raised itself with impetuous and surprising speed in the last twenty years to a previously unknown height of development. Modern surgery no longer stops short at the exterior, but has gone even deeper, and now includes within the sphere of its activity every organ of the human body without exception. And for this mankind is indebted in the first place to Sir Joseph Lister. As far as there is an earthly immortality it must be his, for as long as ever surgery is scientifically discussed his name cannot fail to be mentioned.

H. Tillmanns.

Sir Joseph Lister is not, as has been often stated, a Scotchman. He was born at Upton, in Essex, which was then a pretty suburban village, though it has long since been completely swallowed up in the metropolis, and here the greater part of his early life was spent. His father, Joseph Jackson Lister, was a man of rare ability, who devoted the intervals of business to scientific pursuits. He was a Fellow of the Royal Society, and is best known for his work on the improvement of the microscope, which is embodied in a paper in the *Philosophical Transactions* for 1831, "On some Properties in Achromatic Object-glasses applicable to the Microscope." Other papers of his appeared in the *Philosophical Transactions*, one of which was written in conjunction with the well-known Dr. Hodgkin, who belonged, like him, to the Society of Friends. They were the first to describe the tendency of the red corpuscles of the blood to arrange themselves in rouleaux.

Sir Joseph Lister was thus early imbued with scientific tastes, and learned by example, if he did not inherit by descent, the habit of accurate observation and relentless logic; in short, that capacity for taking pains which has been in a special manner the characteristic feature of his genius. He was educated at a private Quaker school at Tottenham, which numbered amongst its pupils at about the same time the late Mr. William Edward Forster and Dr. Wilson Fox; and afterwards he became a student at University College, London, from which he graduated B.A. at the University of London in 1847. He then entered upon his medical studies at University College, and here he came under the influence of Sharpey, which possibly had something to do with turning his attention, in the first place, to the study of physiology. His first publications appeared in the year 1853, whilst he was still a student, "On the Muscular Tissue of the Skin" and, "On the Contractile Tissue of the Iris." He began his surgical studies just at the close of the career of Liston, one of the last of the brilliant and rapid operators of the last generation; and he was one of the first house surgeons to Mr.—now Sir John—Erichsen. After a very distinguished career at the hospital and the University, where he graduated M.B. in 1852, he went to Edinburgh, to see the surgical practice there. Here he was closely associated with, and soon became deeply attached to the late Prof. Syme, whose daughter he subsequently married. At first he was Mr. Syme's house surgeon, but before long he was appointed Assistant Surgeon to the Royal Infirmary, and Extra-Academical Lecturer on

Surgery, in which capacity he soon attracted to himself a devoted band of admirers. Whilst in Edinburgh he not only published notes of Mr. Syme's cases, but continued to pursue his physiological and pathological researches. Between 1857 and 1860 several papers appeared on a variety of kindred matters, of which the most important are those dealing with the subject of inflammation and that of coagulation of the blood. In 1857 his paper "On the Early Stages of Inflammation" was read before the Royal Society, preceded by two others, one being "An Inquiry regarding the Parts of the Nervous System which regulate the Contractions of the Arteries," and the other "On the Cutaneous Pigmentary System of the Frog." This work remains up to the present time one of the most important contributions to the subject. Various observations on the coagulation of the blood, a much-debated matter at that time, culminated in the Croonian Lecture of 1862, which excited great interest, upsetting as it did most of the accepted notions, and forming the groundwork of much of our modern teaching on the subject. In 1860 Lister was appointed Regius Professor of Surgery in the University of Glasgow, and it was there, surrounded by the typical surgery of the old *régime*, and shocked by the prevalence and fatality of the so-called hospital diseases, that his work in connection with antiseptic surgery was begun. Those, however, who have studied his various writings will not fail to observe how his physiological observations were the precursors of his pathological studies, and these again, as he traced first the appearances and then the causes of inflammation, led on step by step to the association in his mind of the inflammation occurring in open wounds with the action of micro-organisms introduced from without, and so to the crowning performance by which his name will be principally handed down to posterity. He always acknowledged the influence of Pasteur's work on the evolution of his ideas, as has been pointed out by Prof. Tillmanns.

His writings since that time have been chiefly devoted to one branch or another of the subject of the germ theory of disease. They consist of articles scattered about amongst various periodicals, so that it would be a difficult matter to produce a complete list of them. Some are elaborate investigations into the processes of fermentation and the life-history of certain micro-organisms, most of which were carried out before the introduction of the plan of cultivating these low forms of life upon solid media, and therefore involved far greater difficulties than are met with at the present day; others are treatises on the bearing of bacteriology upon surgical treatment.

The controversy which was raised on the first promulgation of his views was very warm, and it took a strangely long time before their acceptance in this country was by any means general. To many educated under the old system, it seemed hard to appreciate, first that there was anything new in the antiseptic system at all, and secondly that the modifications of the details of the treatment in the course of its evolution, did not imply a recession from the principles upon which it was founded. It was a stumbling-block to some that, as knowledge advanced, and as it became recognised that the atmosphere was not, as it had been at first supposed, charged with innumerable particles bearing the germs of putrefaction—the details of the treatment became simpler. By an unlucky chance, the term "spray-and-gauze-treatment" had by some been substituted for the "antiseptic treatment"; and when our German *confrères* started the watchword "fort mit dem spray," and it was enthusiastically taken up here, it was assumed that Lister had shifted his ground. The assumption was, it need not be said, absolutely without foundation. The earliest antiseptic dressings were much more cumbrous than those mentioned by Prof. Tillmanns. The first attempts consisted in making an antiseptic crust of blood and pure carbolic acid which was protected by a sheet of block tin, then followed the use of carbolic acid and oil, and then that of a layer of putty made with carbolic acid; after this came a plaister made of shellac and carbolic acid, and all these preceded the carbolic acid gauze, whilst the use of the spray was for a long time unknown. Lister was always aiming at simplifying the details of the treatment; none regretted more than he did its complications, and no one rejoiced more than he, when he found that he could give up the use of the spray with a clear conscience. His idea, in fact, has always been to make an external wound behave as much like a subcutaneous injury as possible by the simplest practicable means.

The antiseptic system was fairly launched about 1867, and in the year 1869 Lister was appointed successor to his father-in-law in the chair of Clinical Surgery at Edinburgh; and here he continued the elaboration of his system, lecturing to large and enthusiastic classes, numerically much greater than any which can be met with in London, whilst his clinique acquired a world-wide reputation.

In 1877, on the death of Sir William Ferguson, he was appointed Professor of Clinical Surgery at King's College, London, a position which he held till three years ago.

No reference has hitherto been made to the many improvements and modifications in surgical practice with which the name of Lister is associated; but though they may not be of much interest to the general reader, it would not be right to pass them over altogether.

Long before Esmarch introduced his method of bloodless operation on the limbs, Lister was in the habit of obtaining the same result in a less objectionable way, by simply elevating the limb, which, as he has shown, empties itself not merely mechanically, but by means of an active contraction of the arteries consequent upon the altered position. He also was the inventor of a tourniquet for compressing the abdominal aorta, thus diminishing hæmorrhage in operations in the neighbourhood of the hip-joint. He has introduced several new operations to the profession, notably an amputation which bears his name, and an operation for excision of the wrist, which, although it is now almost superseded, was for a long time looked upon as the orthodox method of treatment. He was the first to undertake osteotomy for the purpose of rectifying deformity of the limbs, and the first to advocate a more complete method of operating on cancer of the breast, than had been practised by his predecessors. Another advance associated with his name is that of treating fractures of the patella and other bones communicating with joints, by means of open incisions and wiring, a procedure which, before the introduction of

antiseptic surgery, would have been obviously unjustifiable.

We have hitherto dwelt chiefly upon his scientific work, but such facts as those just mentioned serve to show how largely he has devoted himself to, and how much he has advanced, the practical side of his profession.

It seems almost unnecessary to refer to a list of his honours, which is a very long one, including that of LL.D. Edinburgh, 1878, Hon. M.D. Dublin, 1879, LL.D. Glasgow, 1879, D.C.L. Oxon, and LL.D. Cambridge, 1880. He is Surgeon-Extraordinary to the Queen, and Knight of the Prussian order, "Pour le Mérite," Knight Commander of the First Class Order of the Danebrog, and honorary member of foreign learned societies without number. He was created a baronet in 1883, and last year succeeded Lord Kelvin as President of the Royal Society. It would be more to the point if one could suitably describe the estimation in which he is held by the civilised world, and the enthusiasm he has always inspired amongst those who have come under his immediate personal influence.

AN EXPEDITION TO RUWENZORI.

A Naturalist in Mid-Africa; being an Account of a Journey to the Mountains of the Moon and Tanganyika. By G. F. E. Scott Elliot, M.A., F.L.S., F.R.G.S. 8vo. Pp. xvi + 413, with 50 illustrations and 4 maps. (London: A. D. Innes and Co., 1896.)

IN 1862 Baron von der Decken discovered on Kilima Njaro a number of plants which are quite different from those of the surrounding country, and are allied to those of the mountains of Abyssinia and the Cameroons, and of the lowlands of the Mediterranean and the Cape. The collections made by the late Joseph Thomson on the lower slopes of the same mountain and on the plateau of Masai-land proved the complex nature of the East African flora, and enabled Sir Joseph Hooker, in a paper which is one of the classics of African literature, to suggest the sources whence its constituents were derived. The interest thus aroused in the geographical affinities of this flora subsequently sent Sir H. H. Johnston and a host of German botanists to undertake detailed work in Kilima Njaro. Still more recently it inspired Mr. Scott Elliot to undertake his adventurous journey to Ruwenzori; for he tells us in his opening page, that the object of his expedition was "to solve the question of botanical areas which on this side of Africa had often puzzled me."

Mr. Scott Elliot left Mombasa in November 1893, and began his march into the interior along the track known as the "Uganda road." His men had been chosen for him by the agents of the British East Africa Company, and the selection does not appear to have been a good one. Mr. Scott Elliott had to dismiss his head man, the terms of whose engagement were at least remarkable; and his opinion of Zanzibari (or "Suahili," as he generally calls them) appears to have been permanently affected by the unsatisfactory character of his men. The narrative takes us rapidly across the country of the Wakamba to that of the Masai, in which the author had the misfortune to lose all his donkeys and their loads. He pressed on to Kavirondo, and thence along the northern shores of the Victoria Nyanza to Uganda. The direc route on to Ruwenzori was unsafe, as Kabbarega the king of Unyoro, was then at war with the British authorities. Anxious to avoid interference from this chief, whom he describes as one of the "ruffians of the sort who always obtain the sympathy of Mr. Labouchere," Mr. Scott Elliot kept southward along the western shore of the Nyanza. Having reached the Kagera River, he followed up this, and crossed Ankole to the southern end of Ruwenzori. This was the main goal of the expedition, and Mr. Scott Elliot spent four months exploring and collecting on the flanks of this snow-capped range. He made several attempts to reach the snow-line, but the nature of the work and illness prevented him. His account of mountaineering in Central Africa is not inviting.

"It was an awful ascent. Sometimes over deep moss, where jagged root-ends of heather seemed to spring out and stab ankles and knees at every step; sometimes through a dense wood of gnarled and twisted heather-trees, fifteen to twenty feet high, and covered with grey lichens, then down a steep little ravine and dense jungle; and things soon became very hopeless. Everything was shrouded in a cold chilling mist, and first one man and then another became knocked up, until at about 10 a.m. I was left alone. I went on by myself till 2 p.m. The effect of mountain sickness was most trying; I could not walk more than fifty yards without stopping to get breath, and by 2 p.m. I was utterly exhausted, and without food or anything to sleep in. This was at about 12,500 feet."

The level at which the author suffered from mountain sickness was unusually low; but it can be easily explained as due to the effects of malarial fever, which renders men liable to attacks of this malady, at elevations at which they would otherwise be safe.

Two of the men who took part in this excursion never recovered from it, and next time Mr. Scott Elliot tried the ascent, he went alone. He succeeded in reaching the height of 13,000 feet, after a weary struggle with rain, and cold and fever. Climbing over some half-buried boulders, he fell and nearly broke his leg; after this, numbed with cold, and shivering with fever, he crawled back to the point where he had left his blanket-bag, when fireless and foodless in the drenching rain, the night passed as "a sort of horrible dream."

Though Mr. Scott Elliot did not reach the summit of Ruwenzori, he reached the Alpine meadows below the snow-line, and this for his purpose was far more important.

From Ruwenzori he returned to the Kagera River at the point where he had left it, and followed it southward through Karagwe, of Speke's description of which Mr. Scott Elliot speaks most highly. He crossed Urundi to the northern end of Tanganyika; he journeyed down the lake by dhow, marched along the Stevenson road to Lake Nyasa, and then returned home by the Zambesi.

Mr. Scott Elliot's book consists of twenty chapters, which may be divided into two groups. The larger of these is devoted to the narrative of the expedition. This gives a most interesting record of a brilliant piece of pioneer exploration, which was carefully planned, was pluckily carried out in spite of exceptional discouragements, and is described with much charm of style and

many touches of dry humour. This part of the work is of high value, as the notes on the country, the sketches of the life of the people, and the account of the incidents of the march, enable one to form a clear and true idea of the present condition of British East Africa.

The second group of chapters (Nos. x., xi., xii., xviii. and xx.) are devoted to the discussion of general topics. These, taken in order of length, and beginning with the longest, deal with transport, meteorology and climate, outfit, botany and geology. The great length at which transport is treated, and the brevity of the chapter on botany, remind us of the main disappointment of the book. It is entitled "A Naturalist in Mid-Africa"; but, unfortunately, there is in it more about politics than about nature. The author is the only botanical expert who has travelled in British East Africa since Hildebrandt's journey to Ukamba, in 1877, and hence results of the highest importance might be expected from his labours. The chapter on botany is devoted to an attempt to explain the present distribution of the Africa floras. He assumes first, that in Miocene times a sea stretched "across the whole of the desert country which now extends from Beluchistan to the Atlantic, between Morocco and Senegal." But it is practically certain that no such sea has existed since at least Palæozoic times. The second assumption is a use of Körner's thermal constants, to which the author appeals to prohibit the movement of plants along certain directions, and to produce variation by a factor which is almost the same as Romanes' physiological selection. He tells us that in the Victoria Nyanza region, "the rainy season is from October to April. It follows from this that the plants there could not have come from the Congo area, for their climate is a very wet one, and their rainy season is from April to October."

If we are not always converted to Mr. Scott Elliot's theories, we always enjoy his sketches of wild life and of nature. He is seen at his best as an observer. The spirit of the true naturalist comes out in his sketches of life in the woods and on the hillside; and some of his observations, such as on the original limits of the Victoria Nyanza and on the shapes of the valleys of the upper streams of the Nile basin, are of great interest and value. He is always happier when speaking of plants and describing the habits of animals, than when dealing with men. Mr. Scott Elliot takes things sadly, and his quiet humour brings into relief the spirit of sadness that pervades the book. He draws a dismal picture of the conditions of life with a small expedition in Equatorial Africa; and then remarks that on his return people always asked him, "Did you enjoy yourself?" He appears to have been ill-used during his expedition by the officials of both the British East Africa Company and of the German territories. He repeatedly complains that naturalists at home are very inconsiderate of the difficulties of collectors. He grieves that his meteorological notes are of little service, for, as usual, "in the interval between my departure and return, quite new instruments and observations were found to be absolutely essential." In his dedication he describes his book as the "result of a most inconvenient love of botany." In his preface he regrets that he cannot use the map of Ruwenzori prepared from his materials by the Geographical Society, "as several inaccuracies were retained in deference to a more recognised authority than myself." He deplores that "insects are usually collected by travellers, but it is difficult to obtain any information about them in this country." Mr. Scott Elliot's complaint appears to be that the collections of English travellers are not described as thoroughly or as well as those of Germans, and that in consequence there is little inducement to Englishmen to undertake scientific exploration.

There are so few men willing to run the risks and spend their money in this work, that we greatly hope that Mr. Scott Elliot's complaints are not to be taken as proof of a widespread evil. British naturalists have exceptional opportunities for obtaining rich harvests of material from abroad; but owing to the neglect of systematic zoology and botany in our educational centres, the number of trained labourers who can work at them is far too few. The loss to science is no doubt very serious; but as it is impossible for a single collector to collect everything, a traveller can protect himself by devoting his attention to groups in which he knows that his materials will not be wasted.

ANALYTICAL CHEMISTRY.

Analytical Chemistry. By N. Menschutkin. Translated from the third German edition by James Locke. Pp. xii + 512. (London: Macmillan and Co., 1895.)

THERE is, perhaps, hardly any branch of chemistry so overstocked with text-books as that of analysis. In the work before us, however, the subject is presented in such a clear and original manner, that it can hardly fail to become as popular in this country as in Germany, where it has already reached a third edition.

In the preface the author states that although general and analytical chemistry are usually commenced together, yet, in his opinion, the study of the former should always precede that of the latter, the best order of attack being general, analytical, organic, and finally physical chemistry. In view of the difference of opinion in this country as to the best lines to follow in the elementary teaching of chemistry, the following remarks of Prof. Menschutkin are of sufficient interest to quote in full.

"The student cannot rightly turn to analytical chemistry until he has obtained a thorough preparation in the general science; and his knowledge of the latter is measured, not by the number of single and isolated facts with which he is familiar, but by the clearness with which he understands the fundamental chemical phenomena and theories. For these reasons I strongly advise the beginner not to devote himself too quickly to analytical chemistry, and my advice is justified by the character which its study must assume if it is to be of value."

Rather more than half of the book deals with qualitative analysis. The metals are grouped, as usual, according to the properties and modes of formation of their sulphides. Under the heading "General reactions," the corresponding compounds of all the methods of a group are given, and then, as "Special reactions," follow the properties of the chief compounds of each element used in analysis. Especial stress is laid upon the fact that every analytical reaction depends upon definite conditions, which must be known and fulfilled for the suc-

cessful performance of any given separation. The analysis of these conditions is one of the most admirable features of the book, complete explanations being given in all cases where the theory of the reactions is known (as in the separation of nickel and cobalt); conditions found to be necessary by experience, for which no theoretical reason can be given, are definitely stated to be empirical. One point emphasised here, to which no reference is made in our current text-books, has reference to the composition of the metallic sulphides obtained in the wet way. It is pointed out that the anhydrous sulphides as obtained in quantitative analysis differ considerably in their properties (colour, rate of oxidation) from the precipitates obtained in the ordinary course of qualitative work, and these differences of behaviour correspond to differences in composition. Thus the precipitates obtained with hydrogen and ammonium sulphides are in many cases hydrated sulphides (R(SH)(OH) rather than RS). The anhydrous sulphides are occasionally formed in solution, and might give rise to confusion in certain cases. Thus, whilst the ordinary hydrated sulphide of manganese is yellow or flesh-coloured, in presence of an excess of ammonia and ammonium sulphide a green precipitate of anhydrous manganous sulphide is sometimes formed, especially from hot solutions. Again, the black precipitate obtained by treating cupric solutions with hydrogen sulphide is Cu_4S_3, and not CuS, as usually stated, the latter substance, according to Prof. Menschutkin, being unknown.

The analytical properties of the rarer metals are briefly treated in separate chapters. It would have added much to the scientific value of the book if this artificial distinction between ordinary and so-called "rare" metals could have been dispensed with. The present stereotyped mode of treatment is the chief cause of the want of knowledge by the average student of the properties and reactions of metals such as gold, platinum, cerium, uranium, and others that can only be conventionally considered as "rare."

The second half of the book deals with quantitative analysis. The descriptions are concise and the methods well chosen, but are hardly sufficiently detailed for the beginner.

OUR BOOK SHELF.

Grundriss der Krystallographie für Studirende und zum Selbstunterricht. By Gottlob Linck. Pp. vi + 252, 482 figures, and 2 plates. (Jena: Gustav Fischer, 1896.)

This book makes no pretence at supplanting such well-known works as those of Groth and Liebisch, but is intended for the less advanced student, and more especially for the chemist, to whom the necessity of some knowledge of crystallography is becoming increasingly felt. Except in one important particular, little attempt is made to break away from old methods of treatment. The thirty-two classes of symmetry are not treated as independent, but crystal symmetry is distributed in the usual way into the six systems, and under each system are described the holohedral, hemihedral and tetartohedral forms. Both the Naumann and the Millerian symbols for the faces are used, but greater prominence is given to the former.

An important innovation, however, is made in the chapter on the optical characters of crystals. Here, we are glad to see, the author has followed the example of Prof. Groth and adopted the purely geometrical treatment involving the use of the "Optical Indicatrix," as devised by Mr. Fletcher.

The book is fairly evenly divided between the two sections dealing respectively with the geometrical and the physical characters of crystals, about a hundred pages being devoted to each. As it is not written for the advanced student, the subject of the calculation and graphic representation of crystals is not touched upon.

The book appears to be well adapted to the purpose for which it is intended. G. T. P.

Cyanide Processes. By E. B. Wilson, E.M. Pp. 116 (New York: John Wiley and Sons. London: Chapman and Hall, Ltd., 1896.)

It is difficult to say with what object this little book has been written, and so it would perhaps be rash to assert that its object has not been attained. It is, at any rate, to be regretted that Mr. Wilson's work ever saw the light, as it is distinctly inferior to each of the half-dozen accounts which have already appeared of the cyanide process for the extraction of gold from its ores, and can only mislead and confuse those who expect to learn something from it. It is evident, from his own statements in the preface and elsewhere, that the author has derived much of his acquaintance with the subject from Patent Office literature, although he also claims to have read extracts from technical journals and other periodicals. He has not touched on mechanical details, but has confined himself to expounding the chemical principles of the process, which he appears to understand very imperfectly. The book is full of mistakes, such, for example, as that "the standard solution of cyanide contains from 0·5 to 1·5 per cent.," and that mercury oxidises quickly in the air at ordinary temperatures. On p. 74 it is stated that "the gold positive dissolves to the cyanide solution negative, with the result that the gold cyanide solution is positive. . . . Whether this electrolyte becomes converted into an electrode by absorbing the gold we are unable to say, but when they become 'cations' the gold is in the metallic state and the potassium cyanide is immediately set free." The book is well supplied with such statements as this. T. K. Rose.

The Treatment of Phthisis. By Dr. Arthur Ransome, M.A., F.R.S. Pp. viii + 237. (London: Smith, Elder, and Co., 1896.)

Medical men will be grateful for this treatise on the treatment of phthisical patients. The first part of the work comprises a general statement on the etiology pathology of phthisis, and the limits of infection; while the second part deals with the special and medicinal treatment of the malady. The contents are largely confined to descriptions of methods of treatment which have been personally used by the author, and results which have come under his own experience; but they, nevertheless, constitute a broad account of the nature and means of combating phthisis, and one which will give physicians brighter views as to the possibility of cure in the disease.

A Text-book of Applied Mechanics. Vol. I. By Alexander Jamieson, M.I.C.E., Professor of Electric Engineering in the Glasgow and West of Scotland Technical College, &c. Pp. 416. (London: Charles Griffin and Co., 1895.)

The influence of Rankine is apparent here; the ground covered is much the same as in Rankine's "Applied Mechanics," but the treatment is more elementary, and the illustrative exercises and diagrams of a modern character.

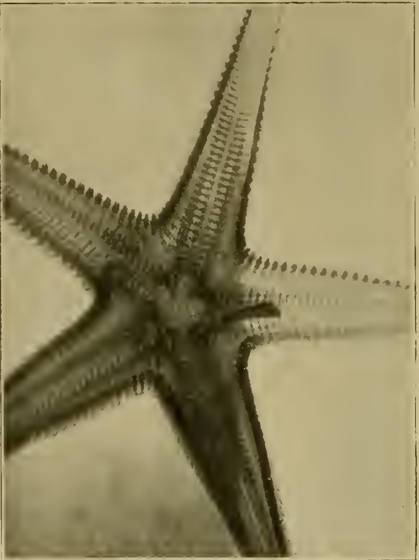
If our writers of elementary school books on Mechanics, all copied from each other and almost exactly alike, could be persuaded to lift their eyes from their own pages and look elsewhere for novelty and reality, they would derive some profit from a treatise such as this. G.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Biological Application of Röntgen Photography.

THE accompanying Röntgen radiograph of *Astrospecten irregularis* was made in the physical department of this college, for a popular lecture on the new photography given by Prof. H. Stroud. It will be seen that not only are the ossicles of the oral surface fairly successfully shown through the thickness of the body and arms, markedly the first of the series of adambulacra, but certain striking and unlooked-for objects appear as well. On dissection the dark conical body to the right proves to be a large piece of the shell of Dentalium lying in one of the cæca of that arm. The oval bodies, one in each of the cæca of the opposite arm, are masses of sand and indigestible material enclosed in the thinned shells of molluscan victims. These are made by the action of the cilia, and form a convenient way of getting rid of the useless matter by way of mouth. The minute anus, indeed,



Astropecten irregularis.

is quite inadequate, and is doubtless used more for fluid than solid evacuation. The madreporite plate and stone canal are seen in the inter-radius below and between the bodies referred to; and the position of the stone canal was in fact the guide in determining their position. The darkish mass in the cæcum to the left of the stone canal consists mainly of broken and whole shells of young Cardia. The stomach was filled with a whole common mussel (*Mytilus edulis*), minus the shell, and this is quite transparent. The paxillæ will be seen to occur as dots all over the body and arms. A block of wood, which was laid over part of the star-fish, has evidently only made a part of the picture lighter.

A radiograph of *Solaster papposus*, with the young Cribella, is enclosed for comparison. Though interesting also in regard to the skeletal parts shown, there is nothing calling for further note here, and they were not dissected.

All three were spirit specimens, and were got at St. Andrews some years ago. ALEXANDER MEEK.

Durham College of Science, Newcastle-on-Tyne, April 25.

Barisal Guns.

IN the correspondence on this subject I have not noticed any reference to the noises said to be heard in the mountains of the peninsula of Sinai. In his "Sinai and Palestine" (ed. 1868, pp. 13–14), the late Dean Stanley refers to "the mysterious noises which have from time to time been heard on the summit of Jebel Musa, in the neighbourhood of Um Shaumer, and in the mountain of Nakus or the Bell, so called from the legend that the sounds proceed from the bells of a convent enclosed within the mountain. In this last instance the sound is supposed to originate in the rush of sound down the mountain side. . . . In the case of Jebel Musa, where it is said that the monks had originally settled on the highest peak, but were by these strange noises driven down to their present seat in the valley, and in the case of Um Shaumer, where it was described to Burckhardt as like the sound of artillery, the precise cause has never been ascertained."

Burckhardt ("Travels in Syria and the Holy Land," 1822, p. 591) refers to these noises and says: "The wind and weather are not believed to have any effect upon the sound."

Failand, April 30. EDW. FRY.

The New Education Bill and Libraries, Museums, and Art Galleries.

REFERRING to the letter by "C." in NATURE for April 23, p. 580, I would urge the importance of his suggestion, but would go further and suggest that all institutions in England and Wales supported out of a rate raised under the Public Libraries Acts or the Museums and Gymnasiums Act, should be put under the management and control of the same local authority as may be appointed for elementary, technical and secondary education.

The management of educational institutions cannot be unified so long as such essentially educational work as that done in public libraries, museums, and art galleries does not come under the purview of the local education authority. There should, of course, be conditions inserted in any Bill having the object suggested to secure the expenditure of the rates received under the special Acts referred to, on the support of libraries, museums, art galleries and gymnasiums.

At present the Public Libraries Acts may be adopted and a rate levied, not one penny of which goes to the support of a library or museum. A certain Lancashire local authority applies the rate for purposes which would have been equally covered by the adoption of the Technical Instruction Acts. On the other hand, some public libraries and museums obtain subsidies out of the funds received by corporations under the Local Taxation (Customs and Excise) Act, though usually on condition that strictly educational books or objects are purchased out of the grants given.

I hope this subject will receive due consideration from such parliamentary advocates of scientific education as Sir John Lubbock and the members who act with him.

In conclusion, may I refer all who are interested in this subject to a paper entitled "The Relationship of the Public Library Committee to other Educational Bodies," published in the *Library* (vol. vii. p. 129), the organ of the Library Association of the United Kingdom. JOHN J. OGLE.

Free Public Library, Museum, and Technical School, Bootle, April 28.

Magical Growth of Plants.

I NOTICE in NATURE of April 9 that mention is made of the experiments of M. Ragonneau in connection with what is termed the magical growth of plants. At the time when M. Ragonneau's statements were first brought under my notice, I endeavoured as nearly as might be to repeat his experiments. I first used formic acid diluted 1 : 5000, the strength stated by M. Ragonneau as being that most successfully used by him. The soil was thoroughly dried, and was some which I had carefully prepared for growing Begonia seed. The seeds used were those of the Scotch thistle (*Onopordium Acanthium*), a soft and easily-grown seed. The experiments were carried out in an ordinary greenhouse with temperature ranging from 55° F. to 75° F.; and although I took every precaution to avoid mischance, the seeds have not to

this day shown any signs of life whatever, although seeds from the same packet, planted simultaneously under ordinary circumstances, are now well-grown young plants. After my first failure, I procured pure concentrated formic acid (sp. gr. 1·300) freshly made, and on repeating the experiments with it, other things being the same as in the former experiment, the result was again entirely negative. I then tried various other seeds, first soaking them in water for periods varying from five hours to three days before treating them with the acid, but all with no result. So far as I could judge, the only effect of the acid was to increase the density of the seed and to retard the growth, so much so that some of the seeds (common Lupinus), which under formic acid showed no signs of growth, as soon as they were thoroughly washed and placed under normal conditions began to germinate in the usual way. Since these experiments I have tried many different seeds and many different strengths, but have only so far succeeded in retarding their growth. I also attempted to inject the acid (1·5000) by means of a hypodermic syringe into the substance of growing seeds and bulbs, and in two instances I succeeded in killing a Begonia tuber and an Arum lily, and certainly none of the other plants treated showed the faintest symptom of increased vitality. W. R. M. SEMPLE.

Hendford Park, Yeovil, April 11.

Rooks at Nesting Time.

OPPOSITE my windows are lofty elms on which rooks have established themselves. In one tree there are three nests with sitting birds; a fourth nest, which was built this spring, has never been fully occupied, and a fifth is now in course of construction.

It is in relation to the last two nests that a singular fact is noticeable. A pair of rooks are apparently mated, flying off and returning together, and roosting at night on the same branch.

Both are engaged in building, but on different boughs; both select the same tree, almost the same branch, for twigs, and both return home spray in beak. But while the hen bird flies to the incomplete nest (which she has built up, unaided, from the beginning, and is now three-fourths finished), the cock bird settles on the old nest, at the other side of the tree, and adds an upper story to an already capacious mansion.

How is this binary housekeeping or nest-building to be explained?

There have been further complications in the rookery since I wrote the foregoing a fortnight ago.

Then the situation was that a couple of rooks (apparently paired) were working together in collecting twigs; but while the hen bird carried hers to a new nest on the north side of an elm, the cock took his to an old nest on the south side.

Still they roosted and flew together, and behaved as engaged rooks should do, the cock now and then bringing a twig or two to the hen's nest, but chiefly working on his own.

In a few days the cock brought home another mate, and both birds set to work at the old nest. Although, for a day or two, appearances were still preserved, the original hen at last resented this trifling with her affections; she pecked at and drove off the cock, stole lining from his nest, and has since lived a life solitary and misanthropic. I see no sign of a new mate, but the hen sits by or on her own nest, and routs all new-comers who approach it.

On the same tree I have seen a singular case of wholesale burglary in which the sufferers are the new occupants of the old nest I have referred to, and the burglars a new pair of rooks. For a week they strove and failed to build a nest in an honest way, *i.e.* by breaking twigs from other trees; but they made no progress, the wind repeatedly blowing away the foundation during their absence in quest of materials.

One night, however, the wind dropped. The pair got up very early next morning, fell on the old nest (the tenants having gone off to feed), and by nine o'clock had three parts finished a new nest, on the north-west side, built entirely out of plunder from the old nest. To this they have since added a clumsy top story made of new materials.

One other curious fact, and I will take up no more of your space. On another elm a stray hen had persisted in thrusting her unwelcome attentions on an established pair now feeding their squabs. She had been there some days, and apparently was at last tolerated. One night, however, as many as ten desperate battles took place; the combatants falling, still locked in combat, from the topmost bough almost to the ground, and as often returning to the fray at the nest-side. This morning Aunt Caroline is *non est*, but I expect she will turn up again before long. Meanwhile, due perhaps to the extra food the young birds got by the exertions of the aunt, they are the largest and strongest in the rookery. F. E. BAINES.

Leamington, April 28.

An Auroral Display on May 2.

ON the evening of Saturday, May 2, at Filey (Yorkshire) I observed faint indications of an auroral display as early as 10 o'clock. On going out of the house at 11.10, five streaks of light were seen in the north, and a small cloud of light appeared on the horizon, which quickly rose and formed a perfect bow of light of great length and some 10° above the horizon at its highest point; by 11.15 all the streaks had disappeared. At 11.30, rapid beams of light were seen following the curve of the bow from west to east, each succeeded by straight arrow-like flashes above the bow in the opposite direction; 11.36, streaks again appeared on the eastern side; 11.39, the bow threw off clouds of light radially, first on the western, then on the eastern side; 11.42, the phenomena observed at 11.30 again set in on the western side; 11.49, the bow became very sharp towards the west and threw out streaks of light, while towards the east it became broken and flickering; 11.55, streamers appeared on the eastern side, and the bow became contracted on this side and smaller, striking the horizon at a higher angle; 11.58, the bow thickened and threw off radial clouds again; 12.1, a fine streamer appeared on the extreme eastern side; 12.3, the bow became very irregular, and for the first time the streamers appeared to start below the bow, three very sharp ones forming towards the east; 12.7, a second bow formed below the original one; 12.9, the bow broke up entirely towards the east into fine streamers, radial clouds of light being thrown off in the west; 12.20, bow became very indistinct in the west, and streamers gave place to clouds of light in the east; 12.22, streamers reappeared in the east; 12.25, arc of the bow reformed; 12.27, bow narrowed down and broke into two bows; 12.30, bow became irregular and sank down towards the horizon; 12.37, bow disappeared and faint streamers formed. After this a gradual fading set in, but the light was still visible though feeble at 1 a.m. The atmosphere had been exceptionally clear all through the day. A. E. M.

Felsted School, Essex.

Daylight Meteor, April 12.

THE meteor referred to in NATURE of April 23 (p. 581), was seen by me in Glasgow, low down on the S.E. horizon, at 8.5 p.m. The position of its visible path was carefully noted at the time in relation to a church spire, which it just seemed to touch. On April 27, at 10.30 p.m. the céntre of the full moon was 2° above this point, its declination was therefore 22° 13′ S., and its R.A. on April 12 at 8.5 p.m. was 10h 39m. On account of some intervening shrubs the meteor's path was only visible over a distance of 10°, but the declination seemed to remain unchanged. C. E. STROMEYER.

Glasgow, May 2.

THE ROYAL SOCIETY SELECTED CANDIDATES.

THE following are the names and qualifications of the fifteen candidates recommended by the Council of the Royal Society for election this year:—

SIR GEORGE SYDENHAM CLARKE,

Major, R.E., K.C.M.G., Secretary to the Colonial Defence Committee and Associate Member of the Ordnance Committee. Late Secretary to the Royal Commission on Administration of the Naval and Military Services. Examiner to the Science and Art Department and the Military Education Department. Formerly (from 1871 to 1880) Instructor in Geometrical Drawing in the Royal Engineering College, Cooper's Hill. Joint Author of paper "On some Figures Exhibiting the Motion of Vibrating Bodies, and on a New Method for Determining the Speed of Machines" (*Proc. Roy. Soc.*, vol. xxvi., pp. 157–163), and of a paper "On the Determination of the Rate of Vibration of Tuning Forks" (*Phil. Trans.*, 1880, pp. 1–14). Author of

"Practical Geometry and Engineering Drawing" (1875): "Principles of Graphic Statics" (1879): "Perspective Explained and Illustrated" (1884): "Plevna: a Study of the Operations of 1877" (1880); "Official Report on the Effects of the Bombardment of Alexandria" (1882); "Fortification: Past, Present, and Future" (1890); and of a large number of papers on naval and military subjects.

J. Norman Collie,

Ph.D., Assistant Professor of Chemistry, University College, London. Distinguished as a worker in Organic Chemistry. Author of numerous papers published during the period from 1881 to the present time in the *Proceedings* and *Transactions* of the Royal Society of Edinburgh, *Liebig's Annalen*, the *Berichte* of the German Chemical Society, and the *Transactions* of the Chemical Society. His earlier papers relate chiefly to the study of phosphonium and phosphine derivatives and allied ammonium compounds, their behaviour when decomposed by heat having been thoroughly studied by him. Of late years he has made important contributions to our knowledge of dehydracetic acid, having described a number of very remarkable "condensations," whereby it is converted into pyridine, orcinol and naphthalene derivatives.

Arthur Matthew Weld Downing,

M.A., D.Sc., Vice-President of the Royal Astronomical Society. President of the British Astronomical Association. Superintendent of the *Nautical Almanac*. Author of the following papers, among many others, which have appeared in the *Monthly Notices* of the Royal Astronomical Society:—"Proper Motions of Certain Stars in the Greenwich Seven Year Catalogue for 1864" (vol. xxxviii., p. 514); "On the N.P.D.'s of the Greenwich Seven Year Catalogue for 1860" (vol. xl., p. 85); "The Greenwich Standard Right Ascensions" (vol. xl., p. 162): "The Possible Ten-month Period of Variation in Latitude" (vol. xl., p. 430); "On the N.P.D.'s of the Cape Catalogue for 1880, and on the Greenwich and Cape Mean Systems of North Polar Distances" (vol. xlii., p. 20); "Discussion of the Observations of γ Draconis, made with the Greenwich Reflex Zenith Tube, during the years 1857-75" (vol. xlii., p. 326); "On the relative Motion of the Components of p Eridani" (vol. xliii., p. 263); "On the Orbit of γ Coronæ Australis" (vol. xliii., p. 368); "On the Periodic Time of α Centauri" (vol. xlv., p. 151); "A Comparison of the Star Places of the Argentine General Catalogue for 1875 with those of the Cape Catalogue, 1880" (vol. xlvii., p. 446); "Positions for 1750 and Proper Motions of 154 Stars, S. of −29° dec., from a revision of Powalky's Reduction of the Star Places of Lacaille's Astronomiæ Fundamenta" (vol. xlviii., p. 322); "Discussion of Washington Observations of the Sun, 1875-83" (vol. xlix., p. 431); "Corrections to the Orbit of Juno" (vol. l., p. 487); "The Orbit of Flora, with corrections to Brünnow's Tafeln der Flora" (vol. lii., p. 585).

Francis Elgar,

LL.D., F.R.S.E., Naval Architect and Engineer, Professor of Naval Architecture and Marine Engineering in the University of Glasgow, and Director of Her Majesty's Dockyards. Prof. Elgar has advanced the science of naval architecture by original investigations, notably in the departments of stability and of the structural strength of ships. These are described in papers communicated to the Royal Society, one of which is printed *in extenso* in *Roy. Soc. Proc.* No. 232, 1884. An abstract of the other was read before the Society on January 14, 1886. The first describes an important and novel principle which determines the variation of stability with draught of water, and the second greatly advances the investigation of the straining actions upon ships at sea. Prof. Elgar is distinguished for his acquaintance with the theory and practice of Naval Architecture, and was unanimously elected on that account by the Court of Glasgow University to the "John Elder" Chair of Naval Architectural and Marine Engineering. He is eminently distinguished as a Naval Architect and Engineer, being a Fellow of the late Royal Society of Naval Architecture and Marine Engineering, and Member of Council of the Institution of Naval Architects, Member of Council of the Institute of Engineers and Shipbuilders in Scotland, and Member of the Institution of Civil Engineers. He was appointed in January 1884 by the Council of the Institution of Naval Architects to sit as their representative upon the Committee formed by the President of the Board of Trade to frame rules for regulating the load lines of ships.

Supplementary Certificate.—Is now a representative of the Institution of Naval Architects upon the Technical Committee of Lloyd's Register of British and Foreign Shipping. Was Vice-President of the International Jury in the class of *Matériel de Navigation et Sauvetage*, in the Paris Exhibition, 1889. Is the Consulting Naval Architect for the Cunard Steamers *Campania* and *Lucania*, which are the most powerful and, with the exception of the *Great Eastern*, the largest ships ever built.

Andrew Gray,

M.A. (Glasgow), F.R.S.E., Professor of Physics, University College of North Wales. Examiner in Mathematics for degrees in the University of Glasgow. For five years Private Assistant and Secretary to Sir W. Thomson (Lord Kelvin); for four years Official Assistant to the Professor of Natural Philosophy in the University of Glasgow; and for the last nine years in his present post. Distinguished for his acquaintance with theoretical and experimental physics. Author of the following scientific works and papers:—"Absolute Measurements in Electricity and Magnetism" (1889); "Theory and Practice of Absolute Measurements in Electricity and Magnetism" (vol. i., 1888; vol. ii., in two parts, 1893); "A Treatise on Magnetism and Electricity," shortly to be published; "On the Determination in Absolute Units of the Intensity of Powerful Magnetic Fields" (*Phil. Mag.*, 1883); "On the Dynamical Theory of Electro-magnetic Action" (*ibid.*, 1890); "On the Calculation of the Induction Coefficients of Coils" (*ibid.*, 1892); "On a New Reflecting Galvanometer of great sensibility, and on New Forms of Astatic Galvanometers," jointly with T. Gray (*Proc. Roy. Soc.*, 1884); "On the Relation between the Electrical Qualities and the Chemical Composition of Glass and Allied Substances," Part I., jointly with T. Gray and J. J. Dobbie (*Proc. Roy. Soc.*, 1884) "On the Electro-magnetic Theory of the Rotation of the Plane of Polarised Light" (*Rept. Brit. Assoc*, 1891).

George Jennings Hinde,

Ph.D. (Munich), F.G.S. Studied at University College, Toronto, Canada (1874-75); afterwards (1879-80) studied, under Dr. Karl Zittel, in the University of Munich, where he graduated. Author of numerous papers on Geology and Palæontology, viz.:—"The Glacial and Interglacial Strata of Scarboro' Heights and other localities near Toronto, Ontario" (*Canad. Journ.*, 1877, pp. 28, one plate); "On Conodonts from the Cambro-Silurian and Devonian of Canada and the United States" (*Quart. Journ. Geol. Soc.*, vol. xxxv., pp. 351-369, pl. xv.-xviii., 1879); "On Annelid Jaws from the Cambro-Silurian and Devonian of Canada and the Lower Carboniferous of Scotland (*op. cit.*, vol. xxxv., pp. 370-389, pl. xviii.-xx., 1879); "On a New Genus of Favosite Coral from the Upper Silurian, Manitoulin Island, Lake Huron" (*Geol. Mag.*, 1879, pp. 244-246); "Fossil Sponge Spicules from the Upper Chalk, Horstead, Norfolk" (*Inaug. Dissert.*, Munich, 1880, 8vo, pp. 84, 5 plates); "On Annelid Jaws from Wenlock and Ludlow formations of the West of England" (*Quart. Journ. Geol. Soc.*, vol. xxxvi., pp. 368-378, pl. xiv., 1880); "Notes on Fossil *Calcispongiæ* with Descriptions of New Species" (*Ann. and Mag. Nat. Hist.*, ser. 5, vol. x., pp. 185-205, pl. x.-xii., 1882); "On Annelid Remains from the Silurian Strata of the Island of Gotland" (*Bihang till K. Svenska Vet. Akad. Handl.*, Bd. vii. No. 5, pp. 28, 3 plates, 8vo, Stockh., 1882); "Catalogue of the Fossil Sponges in the British Museum (Nat. Hist.) with Descriptions of New and little-known Species" (4to. pp. 248, 38 plates, 1883); "On some Fossil *Calcispongiæ* from the Well-boring at Richmond, Surrey" (*Quart. Journ. Geol. Soc.*, vol. xl., pp. 778-783, 1 plate, 1884); "On the Structure and Affinities of the *Receptaculitidæ*," &c. (*op. cit.*, vol. xl., pp 795-849, pl. xxxvi.-xxxvii., 1884); "On a New Species of Crinoid with Articulating Spines" (*Ann and Mag. Nat. Hist.*, ser. 5, vol. xv., pp. 157-173, pl. vi., 1885); "On Beds of Sponge Remains in the Lower and Upper Greensands of the South of England" (*Phil. Trans.*, 1885, vol. clxxvi., p. 51, pl. xl.-xlv.)

Supplementary Certificate.—"A Monograph of the British Fossil Sponges" (Palæontographical Soc., Part I., 1887, pp. 1-92, pl. i.-viii.; Part II., 1888, pp. 93-188, pl. ix.; Part III., 1893, pp. 189-254, pl. x.-xix.); "On the Cherts and Siliceous Schists of the Permo-Carboniferous of Spitzbergen" (*Geol. Mag.*, 1888, pp. 241-251, 1 pl.); "On some New species of *Uruguaya* (Carter), with Remarks on the Genus" (*Ann. and Mag. Nat. Hist.*, ser. 6, vol. ii., 1888, pp. 1-12, 1 pl.); "On a True

Deuconid Calcisponge from the Middle Lias of Northamptonshire" (*ibid.*, vol. iv., 1889, pp. 325–358, 1 pl.); "On Archæocyathus, Billings, and on other Genera allied to it, from Cambrian Strata, &c." (*Quart. Journ. Geol. Soc.*, vol. xlv., 1889, pp. 125–148, 1 pl.); "Notes on Radiolaria from the Lower Palæozoic Rocks of the South of Scotland" (*Ann. and Mag. Nat. Hist.*, ser. 6, vol. vi., 1890, pp. 40–59, 2 pl.); "On the Sponge Remains in the Tertiary Strata, near Oamaru, New Zealand" (in conjunction with Mr. W. M. Holmes), (*Linn. Soc. Journ. Zool.*, vol. xxiv., 1891, pp. 177–262, with 9 pl.); "Note on a Radiolarian Rock from Fanny Bay, Port Darwin, Australia" (*Quart. Journ. Geol. Soc.*, vol. xlix., 1893, pp. 221–226, 1 pl.). Has paid special attention to the microscopic structure of Siliceous Deposits and Cherts, and has demonstrated the existence of Sponges, Radiolaria, and other organisms in them, and as largely composing such deposits, of all ages, and from the most distant parts of the world.

Henry Alexander Miers,

M.A. (Oxon), F.G.S., F.C.S., Assistant in the Department of Minerals, British Museum (Nat. Hist.). Has improved the Adams instrument for the measurement of optic axal angles; devised a form of goniometer for measuring the angles of growing crystals; and a stage-goniometer for use with the microscope. Distinguished as a mineralogist and crystallographer, and author of important investigations in crystallography and mineralogy, 1882–94, as under:—"Cerussit von La Croix" *Zeitsch. für Krystall.*, vi.); "The Crystalline Form of Meneghinite" (*Mineral. Mag.*, v.); "Hemihedrism of Cuprite" *Phil. Mag.*, xviii.); "Monagite from Cornwall and Connellite" (*Mineral. Mag.*, vi.); "Crystallography of Bromostrychnine" (*Journ. Chem. Soc.*, xlvii.); "Crystallography of Tricupric Sulphate" (*ibid.*); "Orthoclase from Kilima-n-jaro and Adrelavia, Switzerland" (*Mineral. Mag.*, vii.); "New Cornish Mineral" (*Mineral. Mag.*, vii.); "Zonenformal für Orthogonate Systeme" *Zeitsch. für Krystall.*, xii.); "Crystals for Baric Slag" (*Journ. Chem. Soc.*, li.); "Use of Gnomonic Projection" (*Mineral. Mag.*, vii.); "Calcites, Egremont, Cumberland" (*ibid.*, viii.); "Pyrargyrite and Proustite" (*ibid.*, viii.); "Mineralogical Notes—Polybasite, Aikinite, Quartz, Cuprite, and Locality of Turnerite" (*ibid.*); "Stephanite and Kaolinite" (*ibid.*, ix.); "Sanguinite (new mineral), Krennerite" (*ibid.*); "Ullmannite Tetartohedrism" (*ibid.*); "Student's Goniometer" (*ibid.*); "Orpiment" (*ibid.*, x.); "Cornwall Danalite" (with G. T. Prior, *ibid.*); (with W. J. Pope) "Mittheil. aus dem Krystall Laboratorium des City and Guilds of London Inst." (*Zeitsch. für Krystall.*, xx.); "Spangolite from Cornwall (*Neues Jahresbr. für Min.*, ii.); "Quartz from North Carolina" (*Amer. Journ. Sci.*, xlvi.); "Xanthocanite," &c. (*Mineral. Mag.*, x.); "Spangolite" (*ibid.*, x.); "On a New Method of Measuring Crystals," &c. (*Rept. Brit. Assoc.*, Nature, l.).

Frederick Walker Mott,

M.D. (Lond.), F.R.C.P. Lecturer on Physiology, Charing Cross Hospital. Distinguished as a physiologist. The following are his most important published papers:—"Bacteria, or their Antecedents, in Healthy Tissues" (with Prof. Horsley—*Journ. of Physiol.*, 1883); "Myxofibroma of Spinal Cord" (*Brain*, 1888); "Cardio-vascular Nutrition and its relation to Sudden Death" (*Practitioner*, 1888); "Pathology of Pernicious Anæmia" (*ibid.*, 1890); "Clarke's Column in Man, Monkey, and Dog" (*Journ. of Anat. and Physiol.*, 1887); "On Eye Movements produced by Cortical Faradisation of the Monkey's Brain" (with Prof. Schäfer—*Brain*, 1890, and Internat. Med. Congress, Berlin); "On Movements resulting from Excitation of the Corpus Callosum in Monkeys" (with Prof. Schäfer—*Brain*, 1891); "Complete Sclerosis of Golt's Column" (*Internat. Journ. of Med. Sci.*, 1891); "The Results of Hemisection of the Spinal Cord in Monkeys" (*Phil. Trans.*, 1892).

Supplementary Certificate.—Physiologist and Neurologist. Secretary of the Neurological Society. Pathologist to the London County Council Asylums. Has published the following papers recently:—"The Bipolar Cells of the Spinal Cord and their Connections" (*Brain*, 1891); "Ascending Degenerations of the Spinal Cord" (*ibid.*, 1892); Article on "Pernicious Anæmia" ("Quain's Dict. of Med.," 2nd edit.); "A Case of Multiple Infective Neuritis" (*Clin. Soc. Trans.*); "A Case of Amystrophic Lateral Sclerosis with Degeneration of the Motor Path from the Cortex to the Periphery" (*Brain*, 1895); "Experimental Enquiry upon the Afferent Tracts of the Central Nervous System" (*ibid.*, 1895); "The Sensori-Motor Functions of the Central Convolutions of the Cerebral Cortex" (*Journ. Physiol.*, 1894); "Experiments upon the Influence of Sensory Nerve upon Movement and Nutrition of the Limbs" (Preliminary Communication, with Prof. Sherrington, F.R.S.) (*Proc. Roy. Soc.*, vol. lvii.).

John Murray,

Ph.D. (Jena)., LL.D. (Edin.), D.Sc. (Camb.). One of the Naturalists on board the *Challenger*, 1872–76. First Assistant on the *Challenger* Editorial Staff, 1876–82. Editor and Director of the *Challenger* publications, 1882–95. Editor of the Reports on the Scientific Results of H.M.S. *Challenger*; joint Author of the Narrative of the Cruise of the *Challenger*, and of the Report on Deep-Sea Deposits; Author of a Summary of the Scientific Results of the *Challenger* Expedition; Author of numerous Papers dealing with Oceanography, Physical Geography, and Marine Biology.

Karl Pearson,

M.A., LL.B., late Fellow of King's College, Cambridge. Professor of Mathematics and Mechanics at University College, London. Editor and joint Author of vol. i. of Todhunter's "History of Elasticity." Author of the following papers on Elasticity:—"On the Distortion of a Solid Elastic Sphere" (*Quart. Journ. Math.*, vol. xvi.); "On Twists in an Infinite Elastic Medium" (*Mess. of Math.*, vol. xiii.); "On the Flexure of Heavy Beams" (*Quart. Journ Math.*, vol. xxiv.); "On the Generalised Equations of Elasticity, and their Application to the Wave Theory of Light" (*Proc. Lond. Math. Soc.*, vol. xx.); "On Energy in an Elastic Solid" (*Mess. of Math.*, 1889); "On Wöhler's Experiments on Alternating Stress" (*ibid.*, 1890): also "Contributions to the Mathematical Theory of Evolution" (*Phil. Trans.*, 1894).

Thomas Roscoe Rede Stebbing,

M.A. (Oxon.), B.A. (Lond.). Clerk in Holy Orders. Late Fellow and Tutor of Worcester College. Author of Report on the Amphipoda collected by H.M.S. *Challenger*, a task which has occupied him almost exclusively for six years. It forms three large volumes (vol. xxix. of the Report), and consists of 1774 pages, and 212 plates, with a map, 4to, 1888. (The figures were all drawn by the author.) Also author of the following:—"Note on *Calceola sandalina*, Lmk." (*Geol. Mag.*, vol. x., pp. 57–61, pl. v., 1873); "A New Species of Sessile-eyed Crustaceans" (*Ann. and Mag. Nat. Hist.*, ser. 4, vol. xvii., pp. 73–80, pl. iv.–v., 1876); "Amphipodous Crustaceans (*Hyale, Aronyx, &c.*)" (*ibid.*, pp. 337–346, pl. xviii.–xix., 1876); "Some New and little-known Amphipodous Crustaceans" (*ibid.*, vol. xviii., pp. 443–449, pls. xix.–xx., 1876); "On Sessile-eyed Crustaceans" (*ibid.*, ser. 5, vol. 1., pp. 31–37, pl. v., 1878); "On Species of Amphipodous Crustaceans" (*ibid.*, vol. 11., pp. 464–370, pl. xv., 1878); "The Sessile-eyed Crustaceans of Devonshire" (*Trans. Devon. Assoc.*, vol. xi., pp. 516–524, 1879); "On *Gastrosaccus spinifer*" (*Ann. and Mag. Nat. Hist.*, ser. 5, vol. vi., pp. 114–118, pl. iii., and p. 328, 1880); "A New English Amphipodous Crustacean" (*ibid.*, vol. xv., pp. 58–62, pl. ii., 1885); "On the Crustacea Isopoda of the *Lightning*, *Porcupine*, and *Valorous* Expeditions" (joint paper with the Rev. A. M. Norman, *Trans. Zool. Soc.*, 1886, vol. xii., pp. 77–142, pls. xvi.–xxvii.); "Exotic Amphipoda from Singapore and New Zealand" (*ibid.*, vol. xii., pp. 199–220, pls. xxxviii.–ix.); Address as President of Devonshire Assoc. (*Trans. Devon. Assoc.*, 1884).

Supplementary Certificate.—Author of "The Naturalist of Cumbræ; being the Life of David Robertson, F.L.S., F.G.S., by his Friend" (1891)" "The right Generic Names of some Amphipoda" (*Ann. and Mag. Nat. Hist.*, 1890); "Sessile-eyed Crustaceans" (*ibid.*, pl. xv.–xvi., 1891); "On the genus *Urothœ* and a new genus *Urothoides*" (*Trans. Zool. Soc.*, pl. i.–iv., 1891); "A History of Crustacea" and "Recent Malacostraceæ" (1893); "A New Pedunculated Cirripede" (*Ann. and Mag. Nat. Hist.*, pl. xv., 1894); "The Amphipoda collected during the Voyages of the *Willem Barents* in the Arctic Seas in the Years 1880–84" (*Soc. Nat. Art. Mag.*, Amsterdam, 1894, pl. i.–vii.); "On the Amphipoda of the *Buccaneer*" (*Zool. Soc. Trans.*, 1895, pls. i.–iv.); "Notes on Crustacea"

(*Ann. and Mag. Nat. Hist.*, pl. ii., 1895); "On Four New British Amphipoda (Stebbing and Robertson, *Zool. Soc. Trans.*, vol. xiii., pl. v.-vi., 1891).

CHARLES STEWART,

M.R.C.S., President of the Linnean Society. Conservator of the Museum of the Royal College of Surgeons, and Hunterian Professor of Human and Comparative Anatomy. Late lecturer on Comparative Anatomy, and joint lecturer on Physiology at St. Thomas's Hospital. Distinguished as a Biologist. Author of the following papers :—"On the Structure and Cause of Colour in the Nacreous Layer of Shells" (*Devon. Assoc. Trans.*, 1864); "On the Spicula of the Regular Echinoidea" (*Trans. Linn. Soc.*, 1865); "On a New Sponge, *Tethyopsis columnifer*" (*Quart. Journ. Micros. Sci.*, 1870); "On the Minute Structure of certain Hard Parts of the genus Cidaris" (*ibid.*, 1871): "Note on the Scalp of a Negro" (*Monthly Micros. Journ.*, 1873); "Note on the Calcareous Parts of the Sucking Feet of an Echinus, *Podophora atrata*" (*ibid.*, 1873); "Notes on *Bucephalus polymorphus*" (*ibid.*, 1875); "On the Lachrymal Gland of the Common Turtle (*ibid.*, 1877); "On a New Coral, *Stylaster stellulatus*, and Note on *Tubipora musica*" (*ibid.*, 1878); Note on an Abnormal *Amblypneustes griseus*" (*Journ. Linn. Soc.*, 1880); "On certain Organs of the Cidaridæ" (*Linn. Soc. Trans.*, 1877); "On Some Structural Features of *Echinostrephus molare, Parasalenia gratiosa*, and *Stomopneustes variolaris*" (*Journ. Roy. Micros. Soc.*, 1880); "On a Supposed New Boring Annelid" (*ibid.*, 1881); "On a Hermaphrodite Trout, *Salmo fario*" (*Journ. Linn. Soc.*, 1891); "On a Hermaphrodite Mackerel, *Scomber scomber*" (*ibid.*, 1891); "On Some Points in the Anatomy of *Heloderma*" (*Proc. Zool. Soc.*, 1891); "On a Specimen of the True Teeth of *Ornithorhynchus*" (*Quart. Journ. Micros. Sci*, 1891).

Supplementary Certificate.—Fullerian Professor of Physiology in the Royal Institution.

WILLIAM E. WILSON,

A gentleman who has devoted himself to astronomical research. In December 1870, he was engaged on the Total Solar Eclipse Expedition to Oran. In 1872 he built an astronomical observatory at Daramona and equipped it with a 12" reflector by Grubb. In 1881 he built a new observatory and equipped it with a 24" reflector by Grubb. In 1891 this was remounted and provided with electric control for stellar photography. Author of "A Method of recording the Transits of Stars by Photography" (Roy. Astron. Soc., 1889); "A New Photographic Photometer for Determining the Magnitudes" (*ibid.*, 1892); "On the Radiation of Heat from Sun Spots" (*Proc. Roy. Soc.*, vol. lv.); "The Absorption of Heat in the Solar Atmosphere" (*Proc. Roy. Irish Acad.*, 1892), in conjunction with Prof. Rambaut; "Experimental Investigations on the Effective Radiation from the Sun" (*Phil. Trans.*, 1894), in conjunction with Mr. P. L. Gray; "On the Temperature of the Carbons in the Electric Arc" (*Proc. Roy. Soc.*, 1892), in conjunction with Mr. P. L. Gray.

Supplementary Certificate.—In addition to the qualifications already set forth the following may be mentioned:—(1) Mr. Wilson has undertaken to carry out Experiments on Solar Radiation for the Committee of the British Association; (2) he has written a paper entitled "The Thermal Radiation from Sun Spots" (*Monthly Notices R.A.S.*, vol. lv., No. 8); (3) he has also written on "The Effect of Pressure of the surrounding Gas on the Temperature of the Crater of the Electric Arc" (*Proc. Roy. Soc.*, vol. lviii.).

HORACE BOLINGBROKE WOODWARD,

F.G.S., Geologist on the Geological Survey of England and Wales. Hon. Mem. Norfolk Nat. Soc. and Yorksh. Phil. Soc. Awarded the Murchison Fund by the Council of the Geological Society in 1885. On the staff of the Geological Survey since 1867, and author of the following memoirs :—"Geology of East Somerset and Bristol Coalfields" (1876); "Geology of the Country around Norwich" (1881); "Geology of the Country around Fakenham, &c." (1884); and of parts of five other memoirs; also of parts of sixteen sheets of the map, and of nine sheets of sections. Author of "The Geology of England and Wales" (1876 and 1887); of two papers in *Quart. Journ. Geol. Soc.* (1876, 1886); nine papers, &c., in *Proc. Geol. Assoc.* (1875-1889); of two Presidential Addresses to the Norwich Geol. Soc. (1879, 1880); of eleven other papers published by Norfolk and Somersetshire Societies (1874-1887); of nine papers in the *Geological Magazine*; of Reports on Coast Erosion (Brit. Assoc., 1885, 1889); and of Reports on Pliocene and Post Pliocene Beds to the British Sub-Committee of the International Geological Congress (1882, 1888),

Supplementary Certificate.—Since the above certificate was sent in, Mr. Woodward has been President of the Geologists' Association and of the Norfolk Naturalists' Society. He has also published various papers and memoirs, including the following:—"Formation of Landscape Marble" (*Geol. Mag.*, 1892); "Geological Zones" (*Proc. Geol. Assoc.*, 1892); "Oolitic Iron Ore in Raasay" (*Geol. Mag.*, 1893); "Memoir on the Lias of England" (Geological Survey, 1893).

WILLIAM PALMER WYNNE,

D.Sc. (Lond.), Assistant Professor of Chemistry in the Royal College of Science, South Kensington. Distinguished for his zeal and ability as an organic chemist. Author of "Action o. Sulphuryl Chloride on Acetorthotoluidide and Acetoparatoluidide, Mono-, Di-, and Tri-chlorotoluenesulphonic Acids," and "Note on the Constitution of Nevile and Winther's Orthotoluidenesulphonic Acid and of the Sulphonic Acids of Orthochlorotoluene and Orthobromotoluene" (*Trans. Chem. Soc.*, 1892). Joint Author with Prof. Japp of "Action of Aldehydes and Ammonia on Benzil" (*Trans. Chem. Soc.*, 1886). Joint Author with Prof. Armstrong of twenty-four papers in the *Proc. Chem. Soc.* from 1886-93 on Naphthalene and its Derivatives.

Supplementary Certificate.—Has submitted to the Chemical Society since 1893 papers on the Disulphonic Acids of Toluene and of Ortho- and Para-chlorotoluene (in conjunction with Mr. James Bruce); on the Six Dichlorotoluenes and their Sulphonic Acids (in conjunction with Mr. Alfred Greeves); and eleven communications on Naphthalene Derivatives (in conjunction with Dr. Armstrong). In their communications on Naphthalene (thirty-nine in all) made to the Chemical Society during the past ten years, Drs. Armstrong and Wynne have revised practically the whole of the Chemistry of Naphthalene in so far as relates to the formation of its Chlorinated and Sulphonated Derivatives, and, besides describing many new Derivatives, have placed beyond question the structure of the ten Di- and fourteen Tri-Chloronaphthalenes to which respectively all other Di- and Tri-Derivatives may be referred.

ON LIPPMANN'S COLOUR PHOTOGRAPHY WITH OBLIQUELY INCIDENT LIGHT.

IN the discussion which followed Prof. Lippmann's splendidly interesting communication to the Royal Society (April 23), on colour photography, I suggested the possibility of applying his method to the Röntgen X-light; but at the same time remarked that it might be found impracticable on account of the smallness of the specular reflection of the X-light from polished surfaces, unless at obliquities little short of 90°. Lord Blythswood's experiments, communicated to the Royal Society on March 19, seemed to prove decisively something of true specular reflection of X-light, incident on a plane mirror of speculum metal at 45°. Experiments, which he has since made by means of a concave mirror of speculum metal, have demonstrated beyond all doubt that there is regular reflection at nearly normal incidence; but they have also proved that the amount of regularly reflected light is exceedingly small in proportion to diffuse light caused to emanate from the mirror, by the incidence of X-light upon it. Experiments by Joly, of Dublin, have, I believe, proved somewhat abundant specular reflection of the X-light, at incidences little short of 90°, on surfaces of bodies transparent to ordinary light. And the extremely small refractivity of the photographic gelatine film for X-light, will allow incidences little short of 90° upon the metal mirror, to be used instead of the normal incidences which Prof. Lippmann has hitherto used. But for very oblique incidences the mercury mirror, with its surface fitted to

the not rigorously plane surface of the photographic film, would be unsuitable; and the plan, which Lord Rayleigh described in the discussion, of forming the film on a solid metallic mirror, might be substituted for it.

All things considered, it seems not improbable that Lippmann's process may be applied successfully to X-rays at nearly grazing incidences on metallic mirrors, and possibly even on non-metallic mirrors.

Suppose now, for instance, the directions of the incident and reflected rays to be inclined to the mirror at angles of ·1 of a radian ($5^\circ\!\cdot\!7$). The distance between the planes of stratification in the photograph would be ten times that which would be produced by the same light at normal incidence. Thus if, for example, the wave-length of the particular X-light used is 5×10^{-6} cms. (or one-tenth of that of green light), the photograph would show tints of from green to violet when viewed normally, or at less or more oblique angles, by Lippmann's ordinary arrangements.

It is quite possible, however, that when we know something of the composition of Röntgen light, we may find such great differences of wave-lengths[1] in it, and so much difficulty to obtain approximately homogeneous X-light by sifting through metal plates (as we sift ordinary visible light by coloured glasses), or by other means if other means can be found, that the experiment which I have suggested may fail on account of want of homogeneousness of the incident light.

But here, suggested to me by thinking of oblique incidence for the photographic light, is an illustrative experiment which (with variations of detail to facilitate realisation) cannot fail if Prof. Lippmann will think it worth while to try it. Place a point source of homogeneous violet light (wave-length 4×10^{-5} cms.) so near to the centre of the mirror and sensitive film that rays shall be received at all angles of incidence from zero up to 56° (being the angle of which the secant is 1·788). The thickness of each stratum will vary in different parts of the photograph in simple proportion to the secant of the angle of incidence, and in the centre it will be equal to the half wave-length. It will therefore vary from 2×10^{-5} in the centre to $3\cdot6 \times 10^{-5}$ at the circle of 56° incidence. This photograph, viewed or thrown on a screen as nearly as may be normally, according to Prof. Lippmann's ordinary procedure, will be seen as a complete spectrum in concentric circles, with violet in the centre, and red, of wave-length $7\cdot15 \times 10^{-5}$, at the circle of 56° incidence; but, if viewed by an eye placed at the position of the source of the violet light which photographed it, it will, according to the principles explained by Dr. Lippmann in his paper, be seen of uniform violet light throughout its whole area.

KELVIN.

[1] It is to be hoped however that, very soon, we shall have definite knowledge of wave-lengths of Röntgen X-light by diffraction fringes actually seen instead of estimates of their smallness from diffraction fringes not seen. I should explain that I am writing on the supposition which seems to me, after much correspondence with Sir George Stokes, to be exceedingly probable that Röntgen light is merely ordinary transverse-vibrational light of very short period. That its period is less than one-fifth that of green light seems well proved by the skilful experiments described by Perrin in *Comptes rendus*, January 27, 1896, p. 187; and by Sagnac, *Comptes rendus*, March 30, p. 783.

THE OBSERVATORY AT MONT MOUNIER.

THERE is no end to the generosity of M. Bischoffsheim. Not so very many years ago he endowed science with an observatory at Nice, and now again he has presented another, and this one is at the high altitude of over 8900 feet The observatory is situated on the summit of Mont Mounier, one of the peaks in the Maritime Alps. The advisability of having it at this spot was suggested by M. Bischoffsheim himself.

It was not till early in 1893 that the plans were worked out, but the observatory was sufficiently finished in August of the same year, to allow observations of Venus to be made before the planet passed into its inferior conjunction.

Mont Mounier Observatory (altitude over 8900 feet).

The buildings consist of a house for the astronomer and his assistant, the actual observatory, which has a revolving metallic dome (26 feet in diameter), and a wooden hut, used as workshop or depôt. The house and actual observatory are united by a passage, which is indeed a necessary arrangement, on account of the very severe weather, and the snow, which sometimes lies thickly on the ground.

The observatory is a branch of the one at Nice, and at the time that important observations were being made at Nice, for the purpose of verifying M. Schiaparelli's discoveries on the rotation of the planet Venus, they were simultaneously being carried on at Mont Mounier by M. Perrotin, and with most successful results.

M. Bischoffsheim suggested that the observatory should be a meteorological station; it has therefore been furnished with Richard's recorders, and instruments for ascertaining the temperature, pressure, and other conditions of the air.

Nor is the observatory now isolated. For some weeks the house has been connected by telephone to Beuil, the nearest village with a telegraph office, a distance of five miles. This was also done at the expense of M. Bischoffsheim. It will therefore be possible to send daily reports to the central meteorological office of the observations made on Mont Mounier.

There can be no doubt that the Mont Mounier observatory, started under such favourable conditions, and so well supplied with instruments, will considerably assist in the advance of science.

DR. ADALBERT KRÜGER.

ASTRONOMERS in all observatories and of all nationalities will have learned with regret of the death of Dr. Krüger, the Director of the Kiel Observatory, but who, perhaps, will be more generally recalled as the editor of the *Astronomische Nachrichten*, and gratefully remembered for his services to that journal. From the time that Schumacher, under the auspices of the Danish Government, started the *Nachrichten*, no astronomical journal has proved itself so indispensable, both as a means for the publication of observations and the dissemination of astronomical knowledge, or contributed more to its advance and progress. For that large class of observations of which early publication is its greatest value, but the details of which are a weariness to most editors, the *Astr. Nach.* has stood unrivalled, and its general conduct has wisely preserved the broad lines on which it was originally established. And with the progress of time, as the eagerness of observers has increased with their numbers, Prof. Krüger has recognised the necessity of still more rapid means of communication, and by adding to his manifold duties that of the management of the *Bureau central des dépêches astronomiques*, he has made still further demands on our gratitude, for the ease and certainty with which astronomical discoveries are sent all over the globe, and made available to those who take advantage of the system he has elaborated. Prof. Förster, of Berlin, we believe, early advocated the plan which has proved itself so useful, but the details of the management have been wisely left in the hands of the Director of the Kiel Observatory.

But these services to science, rendered continuously from 1880, when the death of Dr. Peters made vacant both the positions which Dr. Krüger has since filled so admirably, should not put out of sight the fact that he has been both a skilled observer and an ardent astronomer. It is sufficient to recall here his more prominent services, such as the share he took with the late Dr. Schönfeld in the observation of the zones for the *Durchmusterung* at the Bonn Observatory: a work at first voluntarily undertaken on his part, but later in regular and active co-operation with Argelander and Schönfeld. Here, too, during an absence of Dr. Winnecke, which prevented the heliometer being used, he began and carried to a successful issue the determination of the parallax of 70 Ophiuchi, in two very accordant series.

In 1862 Dr. Krüger was appointed Director of the Helsingfors Observatory, in which the instrumental equipment was probably insufficient. There he busied himself with an inquiry into the orbit of Themis, with the view of obtaining a more accurate value of the mass of Jupiter, which the continued observation of that planet is likely to afford. The result, published in the *Proceedings* of the Finnish Society of Sciences, was to show that Bessel's value of the mass of Jupiter, the then received value, required to be increased by the 68/100,000 part, and to give a value intermediate between that of Airy and Bessel, as derived from the motions of the satellites.

From Helsingfors, Dr. Krüger went to the Observatory at Gotha, where he stayed five years, leaving that city to take up his final position at the well-equipped Kiel Observatory, in 1880. For after the termination of the Danish dominion in the Elbe Duchies, the observatory had been enriched by the instruments from the old observatory at Altona, and had been brought into closer relations with the university. This position naturally carried with it the editorship of the *Nachrichten*, to which allusion has already been made. It is true that since the journal has been under his care, the words "Unter Mitwirkung des Vorstandes der Astronomischen Gesellschaft" have appeared on the title-page, but we imagine Dr. Krüger has enjoyed a free hand in its management, with beneficial results to the journal and to his own reputation. In his capacity as Director, he has published many observations of comets, and prepared, or had prepared under his own eye, the orbits and ephemerides of many of these bodies. These computations have been occasionally enriched by notices of a mathematical character, such as the effect of perturbations by planets near the sun. He has also occasionally given original observations of stars observed with comets, and in many useful, if not brilliant, ways, he has shown his capacity as a Director of an observatory. His career has been marked by an energy and industry, to which might be applied the words of Schiller, "Beschäftigung die nie ermattet, die langsam wirkt doch nie zerstört."

NOTES.

THE first of the two annual conversaziones of the Royal Society was held last night, as we went to press.

THE Council of the British Association have resolved to nominate Sir John Evans, K.C.B., Treasurer of the Royal Society, for the presidency at the meeting which will be held next year in Toronto.

THE following fifteen candidates were selected on Thursday last by the Council of the Royal Society, to be recommended for election into the Society:—Sir G. S. Clarke, Dr. J. N. Collie, Dr. A. M. W. Downing, Dr. F. Elgar, Prof. A. Gray, Dr. G. J. Hinde, Prof. H. A. Miers, Dr. F. W. Mott, Dr. J. Murray, Prof. K. Pearson, Rev. T. R. R. Stebbing, Prof. C. Stewart, Mr. W. E. Wilson, Mr. H. B. Woodward, Dr. W. P. Wynne. The qualifications of the candidates will be found in another part of this issue.

THE Surinam Toads (*Pipa americana*), at the Zoological Society's Gardens, have recommenced breeding this year, and two of the females may now be seen with their backs covered with cells, in each of which an egg is located. The hitherto unexplained mode in which the eggs are transferred into their cells has been discovered, and the secret was divulged at the last scientific meeting of the Society.

AN unnamed donor has given Harvard University 100,000 dols. to found a Chair of Comparative Pathology, the only one of the kind in any leading American University.

THE generous hospitality always dispensed to British men of science by continental Governments beggars anything ever done officially in England to welcome foreign visitors distinguished in science. We have already notified that the summer meetings of the Institution of Naval Architects will be held this year in Hamburg on Monday, June 8, and the following day. On Wednesday, June 10, the meetings will be transferred to Berlin, on the invitation of the Imperial German Government, and will be continued there during the remainder of the week. With a public spirit which should put British steamboat companies to shame, the Hamburg-American Company have generously offered to take the members over in a body from Tilbury to Hamburg in their twin-screw Transatlantic liner the *Fürst Bismarck* free of charge. The steamer will start either late on Saturday night, June 6, or else early on Sunday morning, June 7, and will arrive in Hamburg in about twenty hours after its departure. The meetings are receiving the warmest support from the Imperial Government, and the arrangements in Berlin are being carried out by the Imperial

Ministry of the Interior and the Imperial Ministry of Marine. A programme of exceptional interest for the instruction and entertainment of the members is already in course of preparation. The meetings for the reading and discussion of papers will be held in Hamburg in the Bürgerschafts-Saal in the building of the Patriotische Gesellschaft, and in Berlin in the large hall of the Technical High School. Papers have already been promised by the following German members of the Institution:—Herr Dietrich (Privy Councillor), Constructor-in-Chief of the Imperial German Navy, Herr F. Laeisz, President of the Chamber of Commerce of Hamburg, and by Mr. B. Martell and Dr. F. Elgar, amongst other home members of the Institution. It is hoped that the members of the Institution will do all in their power to assist in doing honour to their most hospitable hosts by attending in large numbers.

IT is with sad feelings that we read of the elaborate preparations that have been made abroad to celebrate the centenary of the discovery of vaccination, and reflect that nothing is being done in England to honour Jenner's memory. The *British Medical Journal* says:—On May 14, 1796, Edward Jenner performed the first successful vaccination. The centenary of that event is to be celebrated in a manner befitting its importance in the history of mankind in Germany, Russia, and the United States. In Berlin preparations have been made under the direction of a Committee which includes Profs. Virchow, Gerhard, von Leyden, Robert Koch, von Bergmann, Koenig, Heubner, Langerhans, Proskauer, and other leading representatives of medical and sanitary science, for a great meeting on May 14 in honour of the discoverer of vaccination. There is also to be an exhibition in the Medicinische Waarenhaus (Friedrichstrasse, 108 I, Berlin, N.) of literature, old and new, relating to vaccination, portraits, medals, instruments, &c. In St. Petersburg, the Russian Public Health Society, the Honorary President of which is the Grand Duke Paul Alexandrovitch, has, with the sanction of the Czar, organised a commemoration festival on a still larger scale. On May 14 a "general and solemn" meeting will be held in honour of the discovery. Four prizes will be awarded for the best works on vaccination. An exhibition of objects connected with vaccination will be held. A Russian translation of Jenner's writings, with a biography and portrait, and reproductions of his drawings, will be published under the editorship of Dr. W. O. Hubert. The Council of the Society, with the help of the Government, of provincial and municipal administrative bodies, of scientific societies, and private medical practitioners, has collected materials for a history of small-pox and vaccination in Russia, which will appear at the same time. In the United States arrangements for the celebration of the centenary have been made by a conjoint Committee appointed by the American Medical Association and the American Public Health Association. The celebration is fixed for May 7, the third day of the meeting of the American Medical Association at Atlanta, and the whole of that day will be occupied by addresses and discussions on Jenner and vaccination. Truly is a prophet without honour in his own country when that country is England.

SIR JOHN GORST stated in the House of Commons, on Thursday last, that arrangements are being made to open the Geological Museum in Jermyn Street on Sundays, but the continuance of the practice will depend upon how far the number of visitors appears to justify it.

THE *Botanical Gazette* has passed into the possession of the University of Chicago. It is not, however, to be the botanical organ of the University, but will be freely open, as before, to botanists of all parts of the globe. The object of the change is to secure permanence and possibility of development. The old editors, Prof. J. M. Coulter, Prof. C. R. Barnes, and Prof. J. C. Arthur, remain.

WE learn from the *Botanical Gazette* that the recent "Culver gift" of one million dollars to the University of Chicago for biological endowment has resulted in the establishment of a Department of Botany, in which Dr. John M. Coulter has accepted the head professorship. A large building, to be known as the "Hull Botanical Laboratory" has been planned, and its erection will soon be begun. The four stories of this building will contain ample space for lecture-rooms, libraries, laboratories, and private research rooms for morphology, physiology, and taxonomy. Above the fourth story a large roof-greenhouse will supply an abundance of living material under all conditions As the building will not be completed before April 1897, the full botanical staff will not be organised before the autumn of that year.

DURING the last few weeks some experiments in sea-fish hatching have been carried on at the Port Erin Biological Station, for the Lancashire Sea Fisheries Committee. Prof. Herdman has erected a series of wooden tanks and sand filters, through which the water is passed by the action of a water-wheel worked by the fresh-water tap. The Sea Fisheries steamer, *John Fell*, spent several days at Port Erin trawling for the spawning fish. The ova were fertilised on board, and then conveyed to the tanks. The first batch of young fish ("witches" or white soles) were hatched out on April 29, exactly seven days after fertilisation; and there are now in the tanks, far advanced in their development, lemon soles, witches, and grey gurnards. The work, so far, has been carried out successfully, and the result ought to encourage the Lancashire Committee to realise their project of erecting a sea-fish hatchery near the principal spawning grounds of the Irish Sea.

WE regret to note the death of the Rev. W. C. Ley, on the 22nd ultimo, at the age of fifty-five. He was ordained in 1863, and in 1874 was presented by the Lord Chancellor to the rectory of Ashby Parva, near Lutterworth, which he held until 1892. Mr. Ley had for many years paid special attention to the study of the clouds and the movements of upper air-currents. In 1872 he published an important work on "The laws of the winds prevailing in Western Europe," in which he showed how the preparation of synchronous weather charts, and the accumulating testimony of the universality of the law generally known as Buys Ballot's, connecting wind conditions with the distribution of barometric pressure, had proved some accepted weather theories to be erroneous, and had rendered necessary a new investigation of the general laws. In the year 1879 the Meteorological Council appointed him Inspector of their English stations, and in the following year they requested him to prepare a manual to facilitate the study of the weather in connection with the information supplied by their Daily Weathe Reports. This work, entitled "Aids to the study and forecast of weather," explains clearly the relations of weather conditions to the distribution of areas of both high and low atmospheric pressure. His most recent work, "Cloudland, a study on the structure and characters of clouds," published in 1894, was prepared for press by his son, owing to the serious illness of the author. It embodies the results of his life's work in connection with this subject; the nomenclature is probably too advanced for general adoption, but the treatise contains much valuable information upon the classification of the clouds and the origin of their formation, as well as upon the important bearing of cloud observation on the prognostication of weather. Many papers of minor importance were contributed by Mr. Ley to the *Journal* of the Royal Meteorological Society.

MR. F. E. BEDDARD, F.R.S., gave the first of a course of lectures on the animals in the Zoological Society's Gardens, in the

lecture-room at the Gardens, on Saturday last. The lecture was of an introductory character, explaining the position of Mammals amongst the Vertebrates, and their classification into three main divisions. The extinct Multituberculata and their possible relation to the Monotremes were also spoken of. The course will be continued every Saturday at 4 p.m. until July 4.

At the International Meteorological Conference at Munich, in 1891, a Committee was appointed to consider the question of concerted observations on the direction of motion and the height of clouds. The report of this Committee was made to the International Meteorological Committee at their meeting at Upsala in 1894, the result being that all countries were invited to take part in the investigation of the upper currents of the atmosphere, by means of cloud observations, which are to commence on the 1st prox., and be continued for a year at least. For the use of observers who adopt the international classification recommended at Munich, a standard cloud atlas has been prepared, consisting of about thirty coloured pictures, and is now in course of publication in Paris; while persons who do not adopt that classification are at liberty to use the nomenclature employed in their country. The observations of motion may be made without instruments, or with simple nephoscopes; but the measurements of altitudes require the use of theodolites or photogrammeters, and can only be carried out at regular observatories. Descriptions of the methods to be employed have been published by Dr. Hildebrandsson, of Upsala, and others, and also in *Das Wetter* for February last. Various countries in Europe, the United States, and Java, have undertaken to make the more difficult instrumental observations, and it is recommended by the International Meteorological Committee that the observations from each country should be eventually published *in extenso*, as a separate publication.

The south-east of Europe is one of the most pronounced seismic districts of the world, and it is gratifying to learn that the earthquakes there are to receive the attention they deserve. In a previous note, we have referred to the work of the seismological section of the meteorological observatory at Constantinople, and we have now to announce the formation of a similar section of that at Athens. This has been placed under the charge of Dr. S. A. Papavasiliou, who is well known for his careful investigation of the Locris earthquakes of 1894. Information with reference to Greek earthquakes has indeed been transmitted to the observatory since 1893, and the accounts of these shocks will be published later on. It is only, however, within the last few months that an attempt has been made to organise regular observations. At the observatory of Athens two Brassart seismoscopes of a simple character have been erected, one of them giving the time of occurrence of each shock felt there. The officials at the meteorological stations and telegraph offices (twenty-three in number) have been instructed to make observations, and forward their registers to the observatory; and, commencing with this year, a monthly seismological bulletin has been started. The number for January has just been published, and tends to confirm Dr. Papavasiliou's estimate that hardly a day passes without an earthquake being felt somewhere in Greece, for no less than thirty-four are recorded as occurring during January alone. The most interesting is an after-shock, on the 24th ult., of the great earthquakes of April 20 and 27, 1894, showing a still further displacement of the epicentre towards the W.N.W. along the great fault formed at the time of the last-mentioned shock.

In Tunbridge Wells, on Saturday last, a congress was held of the naturalists of the South Eastern District, with the object of forming a Union of Natural History Societies for mutual help and investigation. The idea originated with Dr. George Abbott, who carried out all the preliminary details for the congress. The first part of the day was taken up by the delegates inspecting the geological features of the town, and after luncheon they assembled in the Pump Room, where the congress was held, under the chairmanship of the Rev. T. R. R. Stebbing, President of the Tunbridge Wells Natural History and Philosophical Society, and whose name is amongst those selected for election into the Royal Society. A large number of delegates from important Natural History Societies of the south-eastern counties of England were present. Dr. Abbott described how the Union could be of assistance to science. Each Society in the Union would offer its members (1) free admission to their lectures and excursions; (2) copies of their Transactions; (3) the use of their library; (4) assistance in naming of specimens, and with the formation of school museums. The corresponding members, in return, would be asked to (1) forward surplus natural history specimens to their Societies' Museum; (2) supply prompt information on the following subjects: (*a*) new geological sections: (*b*) details of wells, borings, springs, &c.; (*c*) finds of geological and antiquarian interest; (3) answer such questions as the British Association or the local Society may require; (4) keep an eye on historic buildings; (5) assist the Selborne Society in carrying out its objects. Such appointments would be certain to stimulate individual investigation in the parishes, and useful scientific work would be done. After a discussion, the following resolution was adopted: "That the delegates from various scientific Societies of Surrey, Kent, and Sussex, assembled in congress at Tunbridge Wells on April 25, 1896, agree that the congress shall meet annually, by invitation, at the home of one or other of the associated Societies." The Rev. T. R. R. Stebbing was elected President of the Union, and Dr. Abbott, Secretary. It was agreed that Surrey, Kent, Sussex, Middlesex, and Hampshire should be included within the scope of the Union's operations.

An extremely interesting series of experiments on the action of a powerful magnetic field on the kathodic rays in Crookes' or Hittorf's tubes, is described by Herr Kr. Birkeland in the *Elektroteknisk Tidsskrift* (Christiania). These experiments prove that in such a field, the kathode rays are strongly deflected in the direction of the lines of force, and can even be concentrated on to the surface of the tube until the glass melts. Moreover, the evidence suggests that the rays which emanate from one and the same kathode fall into groups, of which the physical constants are connected by some definite law, just as are the frequencies of the different tones emitted by a vibrating rod. The investigation has an important bearing on the theory of the Aurora Borealis. The Danish meteorologist, Herr A. Paulsen, is of opinion that the aurora owes its origin to phosphorescence of the air produced by kathodic rays in the upper strata of the atmosphere, and Herr Birkeland suggests that the earth's magnetism may be the cause of this phosphorescence becoming intensified in the neighbourhood of the terrestrial poles.

Under the editorship of Mr. F. S. Macaulay, of St. Paul's School, the first number of a new series of *The Mathematical Gazette* has just been issued by the Association for the Improvement of Geometrical Teaching. The size of the pages has been changed from quarto to demy octavo; by this change the *Gazette* has been brought into uniformity with the leading English and continental mathematical and other scientific octavo publications. The present number contains articles on "The Geometrical Method," by Dr. J. Larmor, F.R.S.; "Annuities treated without Progressions," by Dr. G. H. Bryan, F.R.S.; and "The Conic determined by Five Given Points," by the editor; together with a large number of problems and solutions. The *Gazette* deals exclusively with points of interest in the history and teaching of elementary mathematics (not extending beyond the Calculus), and it thus covers a somewhat different range of

subject-matter to any other mathematical journal in the United Kingdom.

MESSRS. DULAU AND CO. have just issued a catalogue (No. xv.) of works on geographical botany, containing more than four thousand titles, offered for sale by them.

THE Appendix of "Quain's Elements of Anatomy" (Longmans, Green, and Co.), which completes the tenth edition of the work, has now been published. The subject, "Superficial and Surgical Anatomy," is treated by Profs. G. D. Thane and R. J. Godlee.

WE learn from the current (and final) number of the *American Meteorological Journal*, that the New England Meteorological Society has been dissolved. It was formed in Boston, in June 1884, to promote the study of atmospheric phenomena in the New England States, and to establish systematic observation. It has done much useful work, especially relating to rainfall, thunderstorms and range of temperature, the results of which have from time to time been published in the above-named journal. The system of regular meteorological observations and the publication of a monthly bulletin were transferred to the New England Weather Service, in connection with the Washington Weather Bureau, several years ago.

THE Rebman Publishing Company have issued the first number of the *Archives of Clinical Skiagraphy*, by Mr. Sydney Rowland, being the commencement of a series of collotype illustrations, with descriptive text, illustrating applications of the new photography to medicine and surgery. In an introduction Mr. Rowland gives a brief account of Röntgen's discovery, and describes the great advantages obtained by the use of the form of Crookes' tube known as the focus tube, devised by Mr. Herbert Jackson. The excellent results obtained by British investigators working with X-rays are almost entirely due to the introduction of this form of tube. As to the constitution of fluorescent screens, Mr. Rowland agrees with the conclusion arrived at by Mr. Jackson after a systematic examination of numerous substances, viz. that the best salt to use is platinocyanide of potassium. The plates included in the present number of the *Archives* show the skeleton of a full-grown child, aged three months (exposure fourteen minutes), a needle embedded in a finger (exposure two minutes), knee-joint, from a case of multiple exostosis (exposure nine minutes), and hand of same case (exposure three minutes), wrist and forearm showing syphilitic disease of radius (exposure six minutes). The illustrations may be taken as an indication of how the Röntgen photography is able to supplement diagnosis in all cases of bony disease. It is really astonishing to think that, though Prof. Röntgen's discovery is but a few months old, it has already taken its place among the approved and accepted aids to diagnosis, and a publication has been started to deal with its developments in medicine and surgery.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♂) from India, presented by Mr. E. Turnham; a Fennec Fox (*Canis cerdo*) from Egypt, presented by Mr. J. G. Mackie; a Mexican Skunk (*Mephitis macrura*) from Mexico, presented by Mr. Henry Heath Cochrane; a Brahminy Kite (*Haliastur indus*) from India, presented by Mr. A. Kemmis-Betty; an African Tantalus (*Tantalus ibis*), a Leopard Tortoise (*Testudo pardalis*) from East Africa, presented by Captain Dugmore; a Canary Finch (*Serinus canarius*) from Madeira, presented by Mr. H. B. Hewetson; a Great Wallaroo (*Macropus robustus*, ♀), a Gould's Monitor (*Varanus gouldi*), a Black and Yellow Cyclodus (*Cyclodus nigroluteus*) from Australia, a Yellow-headed Conure (*Conurus jendaya*), two Brazilian Tortoises (*Testudo tabulata*) from Brazil, five Meyer's Parrots (*Pœocephalus meyeri*), two Alario Sparrows (*Passer alario*) from South Africa, a Brown-throated Conure (*Conurus æruginosus*) from South America, deposited; a Chimpanzee (*Anthropopithecus troglodytes*, ♀) from West Africa, a Red-naped Fruit-Bat (*Pteropus funereus*), —— Bandicoot (*Perameles* ——) from Australia, two Spotted Tinamous (*Nothura maculosa*) from Buenos Ayres, purchased.

OUR ASTRONOMICAL COLUMN.

THE PLANET MERCURY.—An unusually good opportunity of observing the planet Mercury with the naked eye, or with an opera-glass, will be afforded about the middle of the present month. The planet will be at its greatest eastern elongation on May 16, when it will be 22° from the sun, and will remain above the horizon for two hours and a quarter after sunset. At this time the apparent diameter of the planet will be 8″, and about 0·4 of the disc will be illuminated. On May 14, at 6 p.m., the planet will be in conjunction with the moon, Mercury being 2° 24′ to the south; at 9 p.m. on the same evening, the crescent of the two days' moon will be about 3° N.N.E. of the planet.

COMET SWIFT 1896.—The following continued ephemeris for the new comet is from revised elements computed by Dr. Schorr for Berlin midnight:—

	R.A. h. m. s.	Decl. ° ′	Brightness.
May 8	2 12 41	+62 58·1	
10	1 58 52	64 46·1	0·35
12	1 44 41	66 17·4	
14	1 30 19	+67 33·9	0·26

The unit of brightness is that on April 16. The comet was easily visible in a three-inch telescope on April 30, when the computed brightness was 0·7.

NEW DIVISIONS OF SATURN'S RINGS.—In the current number of the *Comptes rendus*, M. Flammarion gives particulars of some very interesting observations of Saturn's rings which have been made at his observatory by M. Antoniadi during the last month. Between the Cassini division and the Crape ring, three new divisions of the ring have been noted. The darkest of these, which is easily visible when the air is transparent, nearly bisects the inner bright ring; the fainter divisions, one on each side, are only observed with difficulty. The inner bright ring is thus divided into four zones, gradually darkening towards the planet.

This is by no means the first time that divisions of this kind have been recognised. Herschel, De Vico, Bond, Hall, and others, have in turn observed or suspected them, but Cassini's division is the only one which seems to be certainly permanent. M. Flammarion concludes that the fainter divisions observed on the rings are variable, and possibly dependent upon the varying attractions of the eight satellites upon the meteoritic particles of which the rings are composed.

DETERMINATION OF THE GENERAL BRIGHTNESS OF THE CORONA.—In the current number (vol. vi. No. 6) of the *Journal* of the British Astronomical Association, Mr. Joseph Lunt suggests a method by which a numerical value could be obtained for the general photographic intensity of the light of the corona during a total solar eclipse.

The method consists in photographing a "sensitometer window," consisting of twenty-five numbered squares of graduated opacities (like a Warnerke's sensitometer, but with different values). The opacities are so adjusted that an exposure of ninety seconds to full moon-light, which approximates to the coronal light, should yield a negative showing the figure 12. The negative could be obtained either by direct contact with the "sensitometer window" (as in lantern-slide making), or by forming an image of the "window" on the plate by means of a lens. The plates could be standardised by exposure to any standard artificial light or to full moon-light, according to Mr. Maunders' suggestion, in order to reproduce the precise illumination of the sensitometer window given by the corona. The conditions of development of the negatives for comparison should be identical, and the plates used should all be of identical sensitiveness.

The apparatus required is very simple, consisting of a box of square section, about three feet long, closed at one end by a ½-plate dark slide, and at the other by the ½-plate sensitometer,

screened by a dew-cap. A diaphragm in the middle carries a lens to form an image of the sensitometer on the plate. A simpler way is to obtain the negative by direct contact, in which case the sensitometer should be screened from the general sky illumination of the horizon.

OBSERVATIONS ON ISOLATED NERVE.

THE work which Dr. Waller has recently summed up in the Croonian Lecture, is an experimental study of the influence of reagents upon excitable—that is to say, living—protoplasm. The choice of nerve as the most convenient form of living matter in such an inquiry is justified by the consideration that nerve, as is now generally admitted, is practically inexhaustible. That nerve fibre, apart from its end organs, is peculiarly responsive to even slight changes of chemical condition; and, further, that with this tissue there is the advantage of a wide and regular range between minimal and maximal effects. A previous research had shown (*Brain*, 1895) that in nerve, contrary to what obtains in muscle, stimulus and response, cause and effect are proportional, the curve expressing their relation to one another being a straight line. Probably, however, the autographic records of these nerve experiments will afford the most convincing argument for the employment of nerve fibre as a test tissue.

The main principle upon which the inquiry is based is the proposition of Du Bois-Reymond and of Hermann, that disturbed protoplasm is electro-negative to the normal; that excited is electro-negative to resting protoplasm. The excised and still living nerve of the frog gives off to the galvanometer a current, called by Hermann "the current of inquiry," which current, on stimulation of the nerve, undergoes a reversal of direction, the "negative variation," or "current of action." Supposing the nerve to be set up so that the current of inquiry is manifested as a northward deflection of the galvanometer (the arrangement followed in these experiments), the negative variation will be south. It is the magnitude of this negative variation which is taken as the index to the magnitude of chemico-physical change aroused in the nerve under various chemical conditions. To a series of stimuli of uniform intensity and duration, given at regular intervals, the nerve responds by a series of uniform deflections or negative variations, which persist for an indefinite time in the absence of modifying agents. A short series of such normal deflections precedes, in these experiments, the application of a reagent, after which, the stimuli being continued, the effect of the drug appears as increase, diminution, or abolition of the negative variations, as the case may be. The galvanometer deflections are recorded on a slowly-moving photographic plate.

The nerve, it should be said, is enclosed in a moist chamber, and rests on two pairs of electrodes, those leading off to the galvanometer, and a pair of wires from an induction coil by which the stimulations are sent in; these consist of weak tetanising currents of 8 secs. duration, given at minute intervals. Where gases are used, they are simply driven through the nerve chamber by pressure; where drugs in solution are employed, the nerve is removed from the electrodes and bathed in the solution for one minute.

Such is, briefly, the method employed. Of the results hitherto obtained, those which relate to the action of anæsthetics upon living matter will have a wide interest from their bearing upon a great practical issue. There is, of course, no question of the crude application of laboratory experience to therapeutics; yet a test so delicate and regular in its working, cannot but have its value in any estimate of the relative advantages and perils of various anæsthetic agents.

The comparative action of carbon dioxide, of ether, and of chloroform has been studied at length. All these in small quantity produce primary augmentation, and a pretty experiment consists in simply blowing through the nerve chamber, when the characteristic rise is produced by the carbon dioxide contained in the expired air. In larger quantity carbon dioxide gives abolition or diminution (Figs. 5 and 6); several minutes may elapse during which there is no response to the regularly repeated stimuli, but the abolition is not permanent, the deflections reappear, attain to, and for a time surpass their normal size. Ether vapour produces a more prolonged anæsthesia, followed by complete recovery of excitability (Fig. 1). Chloroform vapour gives a still more prolonged and often final abolition, recovery, where it takes place, being much less complete than in the case of ether (Fig. 2). Carbon dioxide added to chloroform counteracts the toxic effect and renders it more perfectly anæsthetic—that is to say, there is complete abolition followed by complete recovery.

Of the many other gases tried, oxygen (Fig. 3), carbon monoxide, and nitrous oxide (Fig. 4) give little or no effect, anæsthesia by the last is probably a carbon dioxide effect.

Passing by many groups of chemical substances of which the action has been tested, we may note merely that the study of the comparative action of haloid salts brings out with much clearness the analytical value of the method.

In regard to the acids, a fundamental question to be determined was as to whether their action upon living protoplasm was in proportion to acidity or to avidity. The answer obtained is to

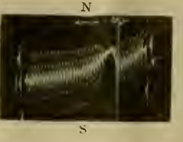


FIG. 1.

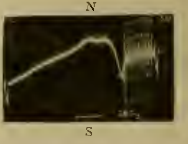

FIG. 2.

the effect that acidity is the chief determining factor. Three acids of widely different avidities, viz. nitric, sulphuric and acetic, have approximately equal effects at the same acid strength. Yet acids have also their specific action, a comparison of, for instance, lactic and oxalic acids of equal strength shows the former to be far more powerful than the latter.

But the most interesting result of these experiments, from the purely physiological point of view, is the demonstration of the evolution of carbon dioxide in the nerve itself. As the chief terminal product of protoplasmic activity carbon dioxide had received a large share of attention, and its influence had been recognised as giving the clue to a curious puzzle with regard to the nerves. In the earlier experiments, when a frog was killed, one sciatic nerve was removed for use, while the other was

FIG. 3. FIG. 4.

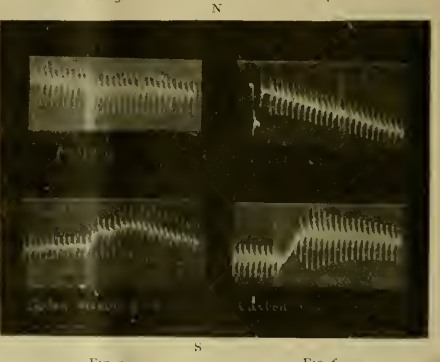

FIG. 5. FIG. 6.

The light band across the plates marks the passage of the gas through the nerve chamber.

left in the body until required. It was noticed that the second nerve was usually more excitable than the first, and when, as sometimes happened, a nerve had been left in the body all night, the negative variation was often a very large, though a declining one. To recognise that this augmentation was due to carbon dioxide given off by the surrounding tissues, was to have a fresh example of the delicacy of nerve as an indicator of the presence of the gas; and the question suggested itself: Supposing carbon dioxide to be evolved during nerve activity, *i.e.* prolonged tetanisation, ought not its presence to be marked by the now familiar augmentation of the negative variation? To test this, recourse was had to a very simple experiment; but before making it, a forecast of its probable course was drawn upon a

black-board. The usual series of normal deflections having been recorded, tetanisation was to be prolonged for five minutes, with the result that the succeeding variations would show an increase which would gradually sink back to the normal. In the actual experiment these anticipations were exactly fulfilled.

Further experiments upon nerve in different conditions (the particulars of which cannot here be described) showed the effect of carbon dioxide as still coinciding with that of prolonged tetanisation, such effect consisting primarily in an augmentation of the negative variation; hence the conclusion is drawn that tetanised nerve evolves carbon dioxide.

In favourable conditions augmentation of the negative variation may be produced by the series of brief tetani employed in the rhythmic excitation of the nerve, when the effect closely resembles the well-known "staircase" phenomenon occurring in contractile tissue. Dr. Waller leaves it an open question whether or no the phenomenon is of carbon dioxide production in muscular as well as in nervous tissue.

Of other sub-positive considerations touched upon, one of chief interest is the surmise as to the functional and chemical relations between grey axis and white sheath in a medullated nerve fibre. The stability of nerve is that of perfect compensation, not that of slowness or absence of change; and it is probable that the investing white sheath supplies the means of rapid repair to the functional grey matter.

It is perhaps not too much to hope that an elucidation of the processes of assimilation and dissimilation will be among the gains to our knowledge of living matter brought about by this new method in the immediate future. S. C. M. S.

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE annual Spring Meeting of the Institution of Mechanical Engineers was held last week on the evenings of Wednesday, April 29, and Friday, May 1. The President, Mr. E. Windsor Richards occupied the chair on both occasions. The meetings were held in the theatre of the Institution of Civil Engineers, lent by the Council of that body for the purpose. The new buildings, which are now being erected for the Institution of Mechanical Engineers, are fast progressing, and probably the present year will be the last during which the latter Society will be dependent for a meeting-place upon the hospitality, always so freely accorded, of the older Institution.

The agenda for the meeting contained two papers, as follows:—

(1) "Steel Steam Pipes and Fittings, and Benardos Arc Welding in connection therewith." By Mr. Samuel MacCarthy, of London.

(2) "Research Committee on the Value of the Steam Jacket. Experiment on a Locomotive Engine." By Prof. T. Hudson Beare and Mr. Bryan Donkin.

The first business of the meeting, the usual formal proceedings having been disposed of, was the reading of his address by the President. Mr. Richards, as is well known, is a prominent steel manufacturer, having held important positions in steel works both in South Wales and in the Cleveland district. As might have been expected, therefore, he dealt more with the raw material which engineers use, rather than the methods of working it up; that is, mechanical engineering proper. It would be ungracious to find fault with the address, which must have involved much labour in its preparation, but the members of the Institution could hardly but feel a little disappointed that the President did not deal more with the machinery used at iron and steel works, rather than with the form of blast furnaces and their products. Mr. Richards' wide experience would have made of the greatest value his remarks on rolling-mills, rolling-mill engines, blowing engines, and many other pieces of machinery which are strictly examples of mechanical engineering used in iron and steel works. However, he elected to confine his attention more particularly to blast furnaces, and his remarks on the subject, although perhaps more in keeping with the other technical society, of which he is a yet more prominent member, the Iron and Steel Institute, were nevertheless of considerable interest. Mr. Richards referred to the delegation organised last year, through the British Iron Trade Association, to visit Belgium and Germany, with a view to ascertaining how it was that these countries were able not only to compete with us in neutral markets, but were also able to sell their products even in our own markets. As the address said, the inquiry undertaken by the delegation involved great labour, and some of our readers may perhaps remember that at the time it stirred up some very angry feelings; the Germans specially resenting what they considered an intrusion into their country. We have not space to follow the President in his discussion upon blast furnace practice in various countries, though it may be generally stated that the Americans show an amount of intelligence and energy in their iron and steel works, which is not surpassed and hardly equalled in any other country. Indeed in blast furnace practice the United States may justly claim to take the leading position in the world, not even excepting ourselves. At the present time near Pittsburgh there is being erected an addition to the Duquesne Works, which will cost about £600,000. Four blast furnaces of a height of 100 feet are being erected, together with the necessary blast engines and other plant. A production of 500 tons of pig-iron every twenty-four hours is expected from each furnace, thus bringing the total product for the year up to the enormous amount of 180,000 tons. Quick working generally means short life in a blast furnace, as in so many other things, and it has been often contended by English iron-makers that the slower working followed in this country is more profitable. If, however, it be allowed that the lining of the new American furnaces only lasts for four years, no less than 700,000 tons of pig-iron will be obtained in that time; a quantity which, as the address pointed out, an English furnace would require fourteen years to produce. Putting aside the question of furnace lining and renewing, it will be easily seen the large advantage a system of quick working gives in respect of labour, establishment charges, and, in fact, all the items that go to make up the cost of producing pig-iron, excepting the raw material. Under these circumstances it is hardly to be wondered at that the American output in the iron trade is advancing with such gigantic strides. Mr. Richards stated that generally in America the whole labour cost per ton of Bessemer pig-iron, is from 80 cents to 1 dol., and it is expected that the new Duquesne plant will reduce that cost by nearly one-half. English manufacturers have, however, perhaps less to fear from competition across the Atlantic, than from that of continental States, and from this point of view the details given of the production of the German and Luxemburg iron districts are of great interest. We do not find the same gigantic output as in America, but "in Germany there is a readiness to adopt new methods, and to take advantage of every point in the game of international competition, which cannot but go far to ensure success." A good example of this is given in the readiness with which German steel makers have adopted the basic process. This process had its origin in England, and though taken up by a few enterprising firms of steel makers, it may be said to have been received with but cold welcome by the trade in general. English makers preferred to import the hematite ores suitable for the acid process, neglecting our own vast resources of ore not suitable for acid steel. The Germans having somewhat similar iron ores, eagerly took up basic steel making, so as to utilise native deposits, and did not rest until they had overcome those defects and difficulties in manufacture, which always attend a new process, and which were, perhaps, exceptionally formidable in this case. They have received their reward, for at the present time an enormous trade is done in Germany in basic steel which can be produced at a cheap rate, whilst the quality is sufficiently good for ordinary engineering purposes. In Belgium, too, we see the result of an intelligent appreciation of modern improvements—both by masters and men—combined with a perseverance and industry which enables advantage to be taken of the smaller details that, in the bulk, go to make success. One thing the English manufacturer has against him is railway rates, and this is very strikingly brought out in a comparison made between the facilities which English manufacturers possess, as against those of the Belgium and German producer. As regards labour cost, Mr. Richards tells us there is not much to our disadvantage, but he says that our labour has become "far more difficult to manage, is much more ready to stop work in order to obtain an increase of wages, and is constantly agitating for fewer hours of work. Every concession made renders it more and more difficult to compete with the continent in the markets of the world, but our workmen cannot yet be brought to see this, neither can they be persuaded to cease opposition to machinery devices for saving labour and reducing cost; indeed all such appliances are jealously watched, and, if possible, their success is prevented." There is much truth in these remarks of

Mr. Richards, and the only cure for the evils he enumerates is to improve the intelligence and the status of the working classes. It is with regret that Englishmen too often see continental employers superior to those of this country in regard to the thoughtful care bestowed upon their workpeople. In some cases it is true, care of the workman is forced upon the manufacturer by legislation, but in a great many instances the continental iron and steel maker has recognised the wisdom of treating his workpeople liberally. Doubtless in England we may find many large-minded employers who, either from self-interest or from motives of a higher character, pay much attention to the well-being of their workmen, but too often the "hands" are looked on as simply an extension of the plant, their sole function being to give the maximum of labour on the minimum of outlay. It is hardly to be wondered at, under these circumstances, that self-seeking persons obtain the ear of the working man in this country, and so often advise them to their own detriment and that of the nation at large.

Mr. Windsor Richards concluded his address with some remarks on technical education. Referring to the want of intelligence on the part of operatives he said, "yet the favourite remedy of this state of things is, in many minds, to spread technical education all over the country; whereas if the results they desired unhappily be attained, the last state of the trade would be worse than the first, for we should have no hewers of coal, nor makers of steel." "Technical education" is so uncertain a quantity that it is not easy to arrive at what Mr. Windsor Richards exactly meant by his expression. We think, however, that his words are likely to be misleading if not mischievous. The most hopeful solution of the labour problem, in fact the only solution, is higher intelligence on the part of the workman, and there is no better way of fostering this intelligence than by giving operatives such knowledge as will enable them to appreciate the processes in which they are engaged. Experience proves that a man does not become less efficient as a labourer, even as a hewer of coal and a maker of steel, because he is educated, although frequently he may, by virtue of his education, rise above these positions. We must, however, leave Mr. Richards' address, and turn to the other parts of the proceedings.

At the last meeting of this Institution, a paper by Mr. W. H. Patchell, on "Steam Superheating" was read, the discussion on which was adjourned until the present meeting. Mr. Patchell's paper referred to various designs of superheater, the principal one treated upon being that of McPhail and Simpson. In this apparatus steam is taken from the boiler and passed to a superheater which utilises the waste gases from the furnace. In this way the steam acquires a certain amount of superheat. It is then taken back to the boiler, and circulates in the water space of the latter by means of an internal pipe. After this it passes to the engine. The object of the invention is to obtain thoroughly dry steam without the risk of it being highly superheated, and thus cutting cylinder faces, or leading to defects which have been experienced in time past in using steam above the temperature normal to the pressure. It will be seen, of course, that this superheater, so called, is not necessarily a superheater at all; it may be, or may not be, the result depending on the quantity of heat imparted to the steam by the waste gases, and to the length of time the steam is subjected to the influence of the water in the boiler by means of the internal pipe. Supposing the steam be superheated several degrees and then returned to the boiler, it will be subjected to the influence of water at a lesser temperature than itself, for the water in the boiler is practically at the temperature of saturated steam due to the boiler pressure. The superheated steam may be reduced to that temperature, but will not fall below it. Practically, we believe, in an installation with a McPhail superheater, as usually designed, the steam finally emerges from the internal pipe at a temperature above that due to its pressure, but generally to a small extent. It will, of course, be dry steam on finally emerging from the internal pipe; though possibly, in some cases, surface radiation in the steam pipe between the boiler and the engine may deprive the steam of its superheat. It is further to be noted that the heat which the superheated steam parts with, to the water in the boiler, is not lost, but goes to aid evaporation. If the degree of superheat of the steam as t passes into the engine cylinder be small, some of the steam will be almost immediately liquefied by the usual process of extraction of heat incidental to the working of any steam engine. If the heat used for superheating be wholly waste heat, there will of course be a gain due to the adoption of the apparatus; but against this must be put the first cost of the superheater. In any case it is an advantage to get dry steam, and the McPhail device must be credited with this.

The principal contribution to the discussion was made by Prof. W. C. Unwin, who claimed that Hirn should be credited with the practical introduction of the use of superheated steam. In Alsace he said superheaters are generally in use, and are found to be of great practical value. If the apparatus were intelligently designed, it was possible to use superheated steam without any of the dangers and troubles of which so much had been heard. A few years ago superheaters were largely fitted to a large number of steamships in the form of the well-known steam chimney, as doubtless the majority of our readers are aware. The advent of higher pressures, and consequent higher temperatures, however, brought difficulties. When steam of 30 to 60 lb. pressure was used, it was possible to increase the temperature of steam above that normal to the pressure, without introducing much complication, but when temperatures rose much above those mentioned, as they speedily did with the advance in boiler practice, superheating became a more serious matter. Improvements in the packing of glands, and the introduction of mineral lubricants, now enabled still higher temperatures of steam to be used without danger. It may be as Prof. Unwin says, that we can take useful example from the Alsatian practice, and thus another era of superheating has arisen. The introduction of the water tube-boiler also may supply an incentive to marine engineers in this direction. The limited water and steam space with this type of generator make it often difficult to get dry steam, so that a superheater would fill a useful place. Another point to be observed is, that if superheating of steam be used, steam jacketing is not necessary, or at any rate not so necessary as when non-superheated steam, often containing a considerable quantity of water, is passed to the engine. Perhaps when the paper on steam jackets by Messrs. Hudson and Donkin is read, we may get further light on this subject, and it is to be hoped ample time will be given for its discussion.

Mr. MacCarthy's paper on "Electric Welding of Steam Pipes" was a valuable and interesting contribution. Higher steam pressures have brought trouble to the marine coppersmith. The old brazed copper pipes have been found, by sad experience, to be dangerous fittings, several lives having been lost by their failure. Steel pipes have been accordingly substituted where high pressures are used; and so far as the pipes themselves are concerned, there is not much difficulty in producing a trustworthy article. The longitudinal welds of a lap-welded pipe are made either by rolls or by the gas-welding system with a hammer, in a thoroughly satisfactory manner, and experience has shown how flanged junctions can be made. It is where joints, such as elbows, T-pieces, &c., are required that the difficulty arises, and it is here that electric welding has come to the help of the marine engineer. On the table of the theatre Mr. MacCarthy exhibited several very fine specimens of steam fittings of the kind referred to, a four-way branch being a notable example. These were all made by the Benardos system of arc welding. Flanges are also welded to the length of pipe in the same manner; the method of working was described by the author as follows:—

"Ordinary low-tension continuous-current lighting dynamos are used; to the terminals of these a battery of Benardos accumulators is connected, into which the current flows continuously. When the welding circuit is closed, the current flows from the dynamos and accumulators; and large resistances are used when necessary. In this way a large discharge is obtained, equal to about twice the capacity of the dynamos, and the load factor of the apparatus is high. For some purposes it is possible to work without accumulators; but when this is done, the efficiency of the apparatus is not so high, because during part of the working period no current whatever is passing, and the machinery is running light."

For attaching the flanges to the pipes, the following method is adopted:—

"The flange is stamped out under the steam hammer in such a way that a V-shaped groove is left on the inside edge, extending about three-fourths through the thickness of the metal. The flange is next shrunk upon the tube, with its flat face outwards or at the end of the tube, and is carefully set in the exact position required. The welding consists in laying small pieces of steel in the V-shaped grove, and welding them in one by one by means of the electric arc, the welds being freely hammered between

each heat. The welder makes a complete circuit of the back of the flange, and fills it up sufficiently to make a fillet of about 1½ inches radius. In this way the flange is solidly welded to the tube at the back, and about three-fourths of the way through its thickness; but the front or outer side is not yet welded. The tube is then up-ended, and the outer side of the flange is welded to the tube, the only difference being that the heat of the arc is used to burn out a cavity all round the junction of the pipe and the flange, until the depth is reached at which the two have already been united; this cavity is then welded up in the same way as the back of the flange, thus ensuring that the flange is welded solid to the pipe right through."

One point in connection with electric work, to which the author called special attention, was the length and size of the arc which is used in the welding of various kinds of work. With a short arc, the carbon point is brought down too close to the steel, and the result is inferior work, not only from the presence of the carbon, but also because the heat is concentrated upon so small a surface that the strains set up in cooling are considerable. The longer the arc, the softer and more defined is the heat; and any slight strain which may be set up can be got rid of by careful annealing. A long arc is therefore indispensable to the proper working of the system.

The reading of this paper was followed by an animated discussion in which trade interests were not altogether neglected. One manufacturer from Sheffield expressed a preference for flanges forged solid from the end of the pipe, rather than for those electrically welded on in the manner described. No doubt the electrical welding gives a very trustworthy attachment between the flange and pipe—experience has proved this; and, equally without doubt, the solid forged flange is an excellent device. The merits of the two systems are reduced to commercial considerations. The same speaker, whilst bearing testimony to the very fine junctions, bends and T-pieces shown by the author, said that recourse to electrical methods for producing these was not necessary, as they could be made equally well, and at a cheaper rate, in the shape of crucible steel castings. That, however, is also a commercial point upon which we need not enter. The question as to whether electrical welding is really welding or fusing, was also discussed by several speakers at the meeting. The problem appears very much to be one simply of names. No doubt electrical welding, as described by the author, is not welding in accordance with the forgeman's old vocabulary; but whether it be welding or fusing, so long as it gives a good and trustworthy junction of the two metals, is a matter of small importance. There is no doubt that electrical fusing, if engineering purists insist on the term, enables work to be done which could not be attempted in any other way, and it will surely take its place in times to come as an engineer's workshop process. The methods of making the longitudinal seams in steam pipes by welding were described by the author in his paper. These methods are well known now, and have been in use for some years, so we need not refer to this part of the paper, further than to state that it gave rise to a discussion on the respective merits of solid drawn tubes made from the ingot (which of course have no longitudinal weld) and lap-welded tubes. On this point Mr. Mark Robinson gave some instructive data. He had made tests with lap-welded steel tubes and solid drawn steel tubes. We will not quote the details, as they were rather voluminous, but we will simply say that the lap-welded tube showed considerable superiority. It may be stated, however, that at the present time seamless steel tubes are being made by one firm in 12 ft. lengths, the diameter being 1 ft.; this is rather a remarkable development of the industry.

The meeting was brought to a close by the discussion on this paper.

The Summer Meeting of the Institution will be held this year in Belfast, and will commence on Tuesday, July 28.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Prof. Sir G. G. Stokes, Prof. A. R. Forsyth, and Prof. J. J. Thomson are to represent the University at the celebration in Glasgow of Lord Kelvin's jubilee next month. Prof. Thomson will also represent the University at the Sesquicentennial celebration of the founding of the College of New Jersey and the inauguration of Princeton University, to be held next October.

In view of the extreme financial depression which has befallen the Colleges, the Chancellor has diminished by £3000 a year the contribution payable by them to the University in 1896–98.

The Council of the Senate has reported in favour of the affiliation of the University of Toronto and the University of Bombay.

Prof. T. W. Bridge and Mr. Charles Davison have been admitted to the degree of Doctor of Science.

OWING to the efforts of the Chairman of the District Council, it will not be long before the town of Bilston is provided with an efficient technical and art school. No less than £2400 has been locally subscribed, and it is confidently expected to bring the amount up to £2500 at least, when it will be possible to claim £1000 from the Science and Art Department, and £500 from the County Council, making a total of £4000. A Committee has been formed in connection with the workmen of the district for raising £250 towards the expenses of furnishing.

SCIENTIFIC study is given a little encouragement by the London Chamber of Commerce. Among the prizes offered for competition in the Chamber's seventh examination for junior commercial education certificates, to be held in the Hall of the Institute of Chartered Accountants, Moorgate-street, E.C., on July 6, are:—Prizes of £5 and £2 for proficiency in commercial history and geography; prize of £5 for proficiency in algebra, Euclid, mechanics, and hydrostatics; prizes of £3 and £2 for proficiency in chemistry; prizes of £3 and £2 for proficiency in electricity and magnetism; prizes of £3 and £2 for proficiency in sound, light and heat; and prizes of £3 and £2 for proficiency in natural history. There will also be awarded the "Princess Louise" prize of £35 for general proficiency, and the "Textile Section" prize of £36 15s. (conditions undetermined); while the Aberdeen Chamber of Commerce offer a prize of £2 2s. for proficiency in mathematics.

AT a meeting of the Technical Instruction Committee of the Cornwall County Council, held at Truro last week, the Agricultural Sub-Committee recommended "That in view of the Government proposals, affecting secondary education, as set out in the Education Bill now before the House, it is desirable to defer taking immediate steps to secure land and premises for the purpose of establishing a farm school in this county." The recommendation, which was proposed by the Chairman, was eventually adopted. During the discussion which took place upon the matter, it was made clear that the original intention had been to found a central institute because the only suitable efficient schools in the county were of a proprietary character, and from the provisions of the Technical Instruction Act, 1889, it was impossible to assist these. The object of deferring the question was to enable the Committee to see if, by the terms of the new Act, schools of only a semi-public character could be assisted, and also to first become acquainted with the powers of the new Educational Committee before they committed themselves to any policy.

A SHORT time ago attention was called in these columns to the low financial condition of the University College, Bristol. We now learn from the *Lancet* that the Council of the College issued last week an urgent appeal for pecuniary assistance to the inhabitants of Bristol and the West of England. The Council earnestly appeal for a capital sum of £10,000 to clear the college from debt, and for an addition to the annual sustentation fund of £700, which would restore the fund to the £1200 subscribed in 1882, not less than which is required to meet the annual expenditure and to secure the Government grant. The Council emphasise the need of a permanent endowment, and suggest that wealthy citizens of Bristol and the West should associate their names, as in other colleges, with the endowment of professorships. The donations already promised for the capital fund amount to £5334, and to the sustentation fund about £100. We note with pleasure that, at a recent meeting of the Technical Education Committee of the Bristol Corporation, it was decided to recommend the Council to make a grant of £2000 to the funds now being raised on behalf of the college, to be conditional upon the £10,000 being obtained, and on the acceptance of two representatives of the Town Council upon the Governing Body.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xviii. No. 2, April. —The intermediary orbit, *i.e.* the Moon's periodic orbit relatively to the Sun obtained from the variation terms when all terms but those depending on the ratio of the mean motions only are omitted, has been considered in vol. i. by Dr. Hill, and subsequently in the *Acta Mathematica* (vol. viii.) the same writer obtained an expression for the motion of the Moon's perigee, so far as it depends on the ratio of the mean motions. These papers have been followed by others by Prof. E. W. Brown, in which the terms depending on the solar parallax and the lunar eccentricity are computed.—The object of the opening paper of the present number, on the inclinational terms in the Moon's coordinates, by P. H. Cowell, is to take into account, according to Dr. Hill's method, the inclination of the orbit, considering it as being the manifestation of a small oscillation about Dr. Hill's distorted circular orbit, which relatively to the Sun is a closed curve. The terms multiplied by the first power of the inclination have been calculated to the sixth order, and an expression for the part of the motion of the Moon's node, that depends upon the mean motions only, has been found as far as the eighth order, *i.e.* one term further than in Delaunay's series. The terms multiplied by the square of the inclination have been calculated to the fifth order, and the terms multiplied by the third power of the inclination to the fourth order in m. The notation adopted is that of the paper by Prof. Brown (*Am. Journ. Math.*, vol. xvii.).—A short note by A. S. Chessin, on non-uniform convergence of infinite series, brings out more clearly a point in a previous note (vol. xviii. No. 1), which the writer says has been misunderstood.—On a certain class of equipotential surfaces, by B. O. Peirce, discusses the nature of such systems of plane curves as are at once the right sections of possible systems of equipotential cylindrical surfaces belonging to distributions of matter which attract, according to the law of nature, and the generating curves of possible systems of equipotential surfaces of revolution.—M. Petrovitch contributes "Remarques sur les équations de dynamique et sur le mouvement tautochrone."—A note on C. S. Peirce's paper on a quincuncial projection of the sphere, by J. Pierpont, corrects an inaccuracy in that paper (vol. ii. p. 394). Mr. Pierpont, in a note on the invariance of the factors of composition of a substitution-group, gives a much simplified proof of this important theorem.—H. Maschke, in a long article (pp. 156-188) on the representation of finite groups, especially of the rotation-groups of the regular bodies of three- and four-dimensional space, by Cayley's colour diagrams, shows that Cayley's method (the theory of groups, graphical representation, *Am. Journ.*, vol. i., and on the theory of groups, *Am. Journ.*, vol xi.) can be readily applied to the construction and investigation of numerous groups of higher orders. In particular, the writer says, the colour diagrams for the rotation groups of the regular bodies can be arranged in such a way that they lend themselves much easier, at least in some respects, to a study of the groups concerned, than even the models of the regular bodies. Numerous diagrams of interest accompany the paper.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, March 19.—Mr. A. G. V. Harcourt, President, in the chair.—The following papers were read:—The constitution of a new organic acid resulting from the oxidation of tartaric acid, by H. J. H. Fenton. The acid obtained by the oxidation of tartaric acid in presence of iron seems to be a dihydroxymaleic acid of the constitution C(OH)(COOH):C(OH)(COOH); an isomeric acid has also been prepared, which is possibly the corresponding dihydroxyfumaric acid.—The volume and optical relationships of the potassium, rubidium and cæsium salts of the monoclinic series, $R_2M(SO_4)_2$, $6H_2O$, by A. E. Tutton. A detailed investigation of the physical properties and volume relationships of the twenty-two salts of this series, of which the author has previously determined the morphological constants, leads to a number of important conclusions; the alkali metal R in salts of this series, exerts a predominating influence on the crystallographical characters of the substances.—Comparison of the results of the investigations of the simple and double sulphates containing potassium, rubidium and cæsium, by A. E. Tutton.—The bearing of the results of the investigations of the simple and double sulphates containing potassium, rubidium and cæsium, upon the nature of the structural unit, by A. E. Tutton. No considerable contraction occurs in the formation of the double salts of the series $K_2M(SO_4)_2$, $6H_2O$ from its constituent salts, so that it is improbable that these constituents are in chemical combination in the solid state; this conclusion is supported by the fact that these salts do not exist in solution, and that many of them are very unstable. It is not necessary to assume that the structural units of crystals consist of more than one chemical molecule in the case of double salts or salts containing water of crystallisation.—The hydriodides of hydroxylamine, by W. R. Dunstan and E. Goulding. The only crystalline hydroxylamine hydriodides which the authors have been able to prepare have the compositions $3NH_3O$, HI and $2NH_3O$,HI.—An analysis of water from the dropping well at Knaresborough in Yorkshire, by B. A. Burrell.—Contributions to the knowledge of ethylic acetoacetate. Part I. Acetonylmalic acid, by S. Ruhemann and E. A. Tyler. Ethylic sodioacetoacetate and ethylic chlorofumarate react with formation of ethylic methyldihydrofurfurantricarboxylate, which on hydrolysis with alcoholic potash yields acetonylmalic acid CMe(OH): CH.CH(COOH).CH(OH).COOH.—The action of lead thiocyanate on the chlorocarbonic esters. Part I. Carboxyethylthiocarbimide and its derivatives, by R. E. Doran.—An auxiliary assay balance, by R. Law. The author describes a balance for assay work, which gives the weight of the gold "cornet" with such accuracy that on its transference to the ordinary assay balance, the observer can put the requisite weight on the balance pan at once; the remaining fraction can then be determined by the rider alone.—Charas: the resin of Indian hemp, by T. B. Wood, W. T. N. Spivey, and T. H. Easterfield. Charas, the resin of *Cannabis indica*, contains a terpene, a sesquiterpene, a paraffin, $C_{29}H_{60}$, and a red oil, $C_{18}H_{24}O_2$; the latter, in doses of 0·05 gram, produces intoxication and sleep.—Note on the decomposition of α-chloronitrocamphor, by A. Lapworth.—On heating α-chloronitrocamphor, camphorquinone is produced.—π-Bromocamphor, by C. Revis and F. S. Kipping.—Oxidation products of α-bromocamphorsulphonic acid, by A. Lapworth and F. S. Kipping. On oxidising ammonium α-bromocamphorsulphonate with nitric acid, products are obtained which seem to be a sulpholactone, $C_{10}H_{12}SO_4Br_2$, a hydroxydibromocamphorsulphonic acid and an ammonium dihydrogen π-sulphocamphoric acid.—On the xylic and xylidinic acids, by W. H. Bentley and W. H. Perkin, junr.

March 26.—Anniversary Meeting.—Mr. A. G. V. Harcourt, President, in the chair.—After the reading of the presidential address and the transaction of the usual business, a ballot was taken for the election of officers and Council for the ensuing year.

Geological Society, April 15.—Dr. Henry Hicks, F.R.S., President, in the chair.—The President announced that a portrait in sepia of Prof. Bonney, executed by Mr. Trevor Haddon, had been presented to the Society by thirty-four subscribers, Fellows of the Society.—The following communications were read:—The Junction-Beds of the Upper Lias and Inferior Oolite in Northamptonshire. Part I. Physical and Chemical, by Beeby Thompson. The author, while combating the view that a considerable unconformity existed between the Upper Lias and the Inferior Oolite of Northamptonshire, brought together much evidence to illustrate the effects of slipping, and to show that these effects may be mistaken for those of unconformity. He also applied the evidence which he had collected to illustrate certain points in the physics of valley-formation. After giving details as to the horizon of the springs of the district, the distribution of water in the Inferior Oolite, and the development of the springs, he argued that every valley of the district has been elongated in the direction which it now has by a stream originating in a spring always at its head, and that the development of channels towards particular points of discharge had been the chief agent in initiating the formation and guiding the direction of all the minor valleys of the river-system within the influence of the same set of beds. A description of the characters of the slopes followed, and their significance was discussed. The structure of the hills and valleys of the district occupied the next portion of the paper, and the author considered that corresponding to the deepening of a valley by denudation there was uplifting of the beds below it, and at the same time an outward and upward thrust along the hillside which lifted beds there; also, that hills were reduced in height by sinking as well as by denudation of their

upper parts. In discussing the question of unconformity between the Inferior Oolite and Upper Lias, the rarity of exposures of true junctions was noted, the junctions which have been chiefly examined by other observers being obscured by slipping; and reasons were given for inferring an absence of unconformity at the horizon, both on account of the character of the true junctions, and from other considerations. The author, however, gave reasons for believing that a slight unconformity occurs in the Upper Lias, so that the lower part of the *jurensis*-zone is absent, and not its upper part, as has been elsewhere inferred.—Contributions to the stratigraphy and palæontology of the *Globigerina*-limestones of the Maltese Islands, by J. H. Cooke. A bibliography of the *Globigerina*-limestones, followed by some remarks on the physical features and general distribution of the strata.—On the geology of the neighbourhood of Carmarthen, by Miss Margaret C. Crosfield and Miss Ethel G. Skeat. The area described lies approximately within a four-mile radius of Carmarthen. The beds of the district have been subjected to complicated foldings, amongst which an earlier set, giving rise to a number of small anticlines with north-and-south axes, and a later more extensive set, due to the series of earth-movements which produced the great Condrusian ridge, producing anticlines and synclines having a general east-and-west trend, can be made out. The rocks forming the subject of the present paper occur in one limb of a complex anticline produced during the latter set of movements. In the discussion that followed, the President congratulated the authors on the important discoveries which they had made. The finding of Tremadoc rocks in the neighbourhood of Carmarthen was a fact of great importance, and might lead to the discovery of still older rocks in that area. The succession closely resembled that found in Pembrokeshire; but it was now carried further east than had previously been done, though the work of the late T. Roberts and Mr. Marr had led to the idea that rocks at least as old as those of Arenig age would be found in this area.

Linnean Society, April 16.—Mr. W. Percy Sladen, Vice-President, in the chair.—Mr. George Massee read a paper on the types of Fungi in the collection of the late Rev. M. J. Berkeley, which was presented to Kew in 1879, and which contains rather more than 11,000 species. Many of the species were described more than fifty years ago; hence the diagnoses are in some cases too brief, and do not embody points which at the present day are considered to be of importance. In many instances this has led to the same species being re-described by others as new. Mr. Massee now supplied careful descriptions of the types, with a view to obviate future confusion, and to secure for Berkeley as the original describer the priority in nomenclature which is justly his.—Mr. A. D. Michael read a paper upon the internal anatomy of *Bdella* (the Red-snouted Mite), giving the results of three years' work and of many hundreds of dissections and serial sections. The material was furnished chiefly from the Zoological Station at Port Erin, and the subject is practically new, only one paper (describing a few parts of the female) having been hitherto published.

Zoological Society, April 21.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—Mr. Sclater exhibited and made remarks on some specimens from Nyasaland, lately sent home by Sir H. H. Johnston, K.C.B. Amongst these was a fine head of the sable antelope (*Hippotragus niger*) from the Zomba plains, and an example of the brindled gnu (*Connochætes gorgon*), or of a nearly allied form, believed to be the first specimen of this antelope sent home from British East Africa.—Mr. Sclater also exhibited, by the kind permission of Mr. Justice Hopley, of Kimberley, a pair of horns of the so-called *Antilope triangularis*, said to have been obtained somewhere on the Zambesi. These horns were now generally supposed to be abnormal horns of the cow eland.—Mr. W. E. de Winton gave an account of a small collection of mammals from Ecuador, lately sent to the British Museum by Mr. L. Söderstrom, H.B.M. Consul at Quito. It contained examples of only three species, but two of these appeared to be new to science. One of them was a new deer, proposed to be called *Pudua mephistophelis*, and the other a rodent of the genus *Icthyomys*, which was named *I. söderstromi*.—Mr. F. E. Beddard, F.R.S., read a paper on the anatomy of a grebe (*Æchmophorus major*), and added some remarks upon the classification of the Charadriiform birds, to which he considered the auks to be more nearly related than to the grebes.—A communication was read from Messrs. F. D. Godman, F.R.S., and O. Salvin, F.R.S., on the butterflies of St. Vincent, Grenada, and the adjoining islands, based on the collections made by Mr. Herbert H. Smith.—A communication was read from Miss E. M. Sharpe containing an account of the Lepidoptera obtained by Dr. Donaldson Smith during his recent expedition to Lake Rudolf. Examples of ninety-one species were obtained, of which two were apparently new. These were described as *Panopea walensensis* and *Papilio donaldsoni*.—A second paper by Miss E. M. Sharpe contained an account of the Lepidoptera obtained by Mrs. E. Lort Phillips in Somaliland. Eighty-four species were enumerated, one of which, *Teracolus ludoviciæ*, appeared to be undescribed.—A communication from Mr. W. F. Kirby contained descriptions of some dragon-flies obtained by Mr. and Mrs. Lort Phillips in Somaliland. Three of these were described as new to science.

PARIS.

Academy of Sciences, April 27.—M. A. Cornu in the chair.—Observations of the Swift comet (April 13, 1896) made with the large equatorial of the observatory of Bordeaux, by MM. G. Rayel, L. Picart, and F. Courty.—Macular or perifoveal œdema of the retina, by M. J. P. Nuel.—New divisions in the rings of Saturn, by M. Flammarion (see p. 17).—Remarks on a communication of M. R. Liouville, entitled "On the rotation of solids," by M. N. Joukovsky. A claim for priority for some Russian mathematicians.—On the transition from the state of flow through an orifice to flow over a weir, by M. Hégly.—On a self-registering thermometer balance, containing either gas or saturated vapour, by MM. H. Parenty and R. Bricard. The two arms of a balance carry respectively a barometer and an air thermometer, both dipping into the same mercury trough. At constant temperature, and with varying atmospheric pressures, the alterations in the weights of the two arms caused by the movements of the mercury are identical, and the balance remains in equilibrium, but an alteration of temperature causes a motion of the beam, which can easily be made self-registering. For a small range of temperature the sensitiveness of the apparatus is considerably increased by substituting a volatile liquid for the gas. The device also readily acts as a temperature regulator.—Mode of action of the X-rays upon a photographic plate, by M. R. Colson. An account of some experiments made with a view to ascertain whether the X-rays impress the photographic plate directly, or whether they are transformed by the glass or film into secondary radiations of a phosphorescent nature, to which the photographic action may be ascribed. All the results pointed to the action being direct, no trace of action due to secondary rays being observable.—On the heterogeneity of the radiations emitted by Crookes' tubes and on their transformation by screens, by M. F. P. Le Roux. The name "hyperdiabatic radiations" is proposed as more suitable than X-rays.—Action of the X-rays upon electrified bodies, by MM. L. Benoist and D. Hurmuzescu. A study of the effect of the nature of the gaseous dielectric in which the electrified substances are placed upon the rate of discharge by the X-rays. The speed of dissipation in air was found to be approximately proportional to the square root of the pressure. At the same pressure the rate of loss of charge with air and carbon dioxide, and air and hydrogen was roughly inversely proportional to the square roots of their densities.—On electrified Röntgen rays, by M. A. Lafay.—Optical superposition of six asymmetric carbon atoms in one active molecule, by MM. P. A. Guye and C. Goudet. The rotations for four divaleryl tartrates of amyl are given, the number calculated from the assumption of the algebraic superposition of the optical effects of the several asymmetric carbon atoms approximates to one of these experimental values.—On a basic nitrate of magnesia, by M. G. Didier. By adding magnesia to a strong solution of magnesium nitrate, the nitrate $Mg(NO_3)_2.2MgO + 5H_2O$ is obtained.—On crystallised sesquiphosphide of iron, by M. A. Granger. Ferric chloride heated to redness in the vapour of phosphorus gives the phosphide Fe_2P_3, which is obtained in the crystalline form if the reaction is carried on slowly.—Study of peridinitronaphthalene, by M. C. Gassmann.—On the tartrate of phenylhydrazine and its derivatives, by M. H. Causse.—Heat of combustion of some cyanogen derivatives, by M. Guinchant. The introduction of the cyanogen group increases the molecular heat of combustion by ninety calories.—On the distillation of the first acids of the fatty series, by M. E. Sorel.—On zeolites and the substitution of the water they contain by other substances, by M. G. Friedel.—On the determination, by a new photometric method, of the laws of luminous sensibility to blacks and greys, by M. C. Henry.—Measurement of odours

in the air, by MM. A. Gerardin and M. Nicloux. The variation in volume of air after treatment with a glowing platinum wire is suggested as giving a measure of bad odours in air.—Statistical researches on the cultivated oyster on the coasts of France, by M. G. Roché.—On the metamorphic gypsums of Algeria, by M. L. Gentil.—The allotropic state of the elementary gases, by M. C. V. Zenzer.—A new general method for calculating the roots of algebraical equations which contain four terms and more, by M. Wisthaler.

DIARY OF SOCIETIES.

FLIGHT.

The Aeronautical Annual, 1896. Edited by James Means. Medium 8vo, pp. 158. (Boston: W. B. Clarke and Co. London: Wm. Wesley and Sons, 1896.)

Zur Mechanik des Vogelfluges. Von Dr. Fr. Ahlborn. Demy 4to, pp. 134. (Hamburg: L. Friedrichsen and Co., 1896.)

TILL quite recently, artificial flight was regarded in much the same light as perpetual motion, the philosopher's stone, and other insoluble problems. But, now that Maxim, Langley, and others have demonstrated the possibility of overcoming the purely mechanical difficulties of flight, a wide field has been thrown open for scientific research in investigating the laws underlying the flight of birds and their practical application to the flight of man. The present record of investigations performed and theories propounded during the past year, will prove of great value to all who are interested in the subject by indicating what work has been done and what still remains undone.

The "Annual" opens with a long account by Lilienthal of recent experiments performed with his new apparatus, in which two superposed wing surfaces are employed instead of one. A description of these experiments was given in NATURE for January 30; but it may be interesting to call attention to the diagram of the undulating path of Lilienthal's machine when raised by a sudden head-wind and again allowed to descend. The motion bears a striking resemblance to that of a model glider allowed to descend in still air, although in the latter case the undulatory course is not due to any wind beyond what the glider makes for itself in its descent.

After a short editorial note on the analogy between the development of the flying machine and that of the modern bicycle, we have a well-written article by Maxim on "Natural and Artificial Flight." Our interest naturally centres round the sections dealing with the author's experiments on the relative advantages and disadvantages of narrow and wide planes. These experiments fully confirm the theory that narrow superposed planes possess greater lifting power per square foot than a single wide plane, a principle which Maxim proposes to utilise most ingeniously in his next machine by constructing his condenser of aeroplanes capable of lifting their own weight + 1000 lb. additional. Maxim, however, doubts whether in an actual machine it may be safe to dispense with wide planes altogether, on account of the risk arising in case of a sudden breakdown. Possibly a suitable compromise may result from adopting the "cellular" principle, which has been introduced with such success in the Hargrave kite. A number of important experiments with this and other kites, notably the "Malay" kite, are described in subsequent articles of the "Annual."

That aerial navigation is regarded as a subject of national importance on the other side of the Atlantic, is evidenced by the Bill introduced into the Senate of Washington on December 4, 1895, to provide for the award of money prizes of 100,000 dols. and 25,000 dols., the first for the successful achievement of mechanical flight, and the second for improvements in soaring machines. The editor of the "Annual" evidently inclines to the view that the final solution of the problem will result from a successful combination of the ingenuity of Lilienthal and Maxim.

Passing now to the flight of birds, we find in the first part of Dr. Ahlborn's memoir a detailed account of the form and structure of birds' wings, and their action in active or "rowing" flight. Marey's observations, in particular, are discussed at some length and freely criticised. The second part deals with the so-called soaring of birds—that is, their power of sustaining themselves continuously in the air without flapping their wings; the term "sailing flight," lately adopted by American writers as a literal translation of the French "vol à voile," is a better name for this action. Unfortunately Dr. Ahlborn's suggested explanation will not bear close examination from a theoretical standpoint. We may take it as an axiomatic consequence of general dynamical principles that when a current of air is blowing uniformly, the relative motion of a bird flying freely is the same as if the current were reduced to rest by applying an equal and opposite velocity both to the air and bird. Starting from this fact, Lord Rayleigh, Prof. Langley, and other investigators have long realised the impossibility of a bird supporting itself without the expenditure of muscular action in a *uniform* horizontal wind, and they have therefore had to seek other sources of energy, either in the variability of the wind velocity, or in local upward convection or other air currents, of which birds have been supposed to take advantage. Dr. Ahlborn, however, seems to hold the opinion that these variations are rather a hindrance than a help to the sailing bird, and that the kinetic energy of the wind is the sole source from which the bird derives its energy. To support this view, the author considers the action of a side wind on a bird sailing round and round in a circle, and he derives his supposed gain of energy by arguments which, though ingenious, are not at all convincing.

The theory of sailing flight is examined from a somewhat more plausible standpoint in the "Annual." Maxim inclines to the view that upward currents of air are the chief cause of the phenomena. Prof. Pickering contributes an article first published in 1889, in which he advocates the theory that the action depends on pulsations or gusts of wind, thus agreeing substantially with the views enunciated subsequently by Prof. Langley in his paper on "The Internal Work of the Wind."[1] Mr. Octave Chanute contributes the first portion of a paper on the subject, but as yet he deals exclusively with observations on sailing birds, and gives no theoretical explanation of their action. We regret that this writer has had to defer till next year's "Annual" his mathematical calculations connected with this singular phenomenon.

With such literature as the "Annual" at hand, the aeronaut should have little difficulty in deciding what experiments will be the most likely to lead to the realisation of artificial flight. G. H. B.

[1] Proceedings of the Aeronautical Congress at Chicago, 1893.

ASTRONOMY AND MILTON.

The Astronomy of Milton's "Paradise Lost." By Thomas N. Orchard, M.D. 8vo, pp. 388. (London: Longmans, Green, and Co., 1896.)

THIS work amounts in fact to a sketch of the history of astronomical discovery under the heads of the different departments of that science to which allusions are made in the great epic of the sublimest of our poets. The author justly remarks that the choicest passages in "Paradise Lost" are associated with these allusions; his main object has been their exposition and illustration, and his enthusiasm has led him to include a wealth of matter in carrying this out, which his readers will not regret. Milton lived in a critical period of astronomical progress. The discoveries of Galileo and Kepler had shown the great probability of the truth of the Copernican system; but Newton had not yet placed that system upon an irrefragable basis. Hence, "in describing the natural phenomena witnessed by our first parents, he adheres to the doctrine of the Ptolemaic system," whilst it is evident from many passages, particularly from the discourse between Adam and the angel in the eighth book, that he saw and appreciated the simplicity and beauty of the Copernican theory, on which he had doubtless conversed with Galileo, the "Tuscan artist," when on his travels in his younger days. All will remember how he represents Raphael as speaking with scarcely-veiled sarcasm of the sphere being supposed to be girded with "Centric and Eccentric scribbled o'er, Cycle and Epicycle, orb in orb," and Adam's difficulty at conceiving "how nature, wise and frugal, could commit such disproportions." Mr. Masson has, we need hardly say, written well on the cosmogony of "Paradise Lost" in the introduction to his edition of Milton; but Dr. Orchard has treated the subject with an abundance of illustration which fully justifies his hope that his contribution to Miltonic literature is both interesting and instructive. A chapter is devoted to the poet's visit to Galileo, and the allusions thereto; it is somewhat remarkable that Milton nowhere mentions the fact that the astronomer was then blind, an affliction which afterwards befell himself. Satan's shield is compared to the glass with which the moon was viewed from the top of Fesolé, a suburb of Florence, or in Valdarno, meaning the valley of the Arno in which that city was situated. Less pertinent to his subject is the sketch of the discoveries of Herschel and others in the sidereal heavens or the region of the fixed stars, of which scarcely anything was known until long after the time of Milton, the date of W. Herschel's birth being exactly a century after the poet's visit to Florence. Dr. Orchard does not seem to have disabused himself of the so-called island theory of the nebulæ, which, it is now clear, have some relation to our own galactic system; but, on the whole, his survey of the history of sidereal astronomy is accurate. There are many allusions in "Paradise Lost" to the starry host "spangling the hemisphere"; and one fine passage speaks of their motions "regular then most when most irregular they seem," which, however, may refer chiefly to the planets, and only by analogy to other systems conceived as probably existing, but not then known. Three constellations (besides the cluster of the Pleiades) are mentioned by name: Taurus, Ophiuchus, and Andromeda, the "fleecy star" near the last being generally supposed to be Aries or its principal star, though this is not certain. Much more frequent allusion is made in the poem to the sun than to any of the other orbs of the firmament, and that body is described "in a manner worthy of his unrivalled splendour and of his supreme importance in the system which he upholds and governs." Probably few passages in any poem are more familiar to all than Satan's address to the great luminary, whose beams the spirit of evil is appropriately represented as hating. Venus is alluded to under the name Hesperus, and as the evening star; and the Galaxy or Milky Way is described as "a broad and ample road, whose dust is gold and pavement stars." As to comets, they are twice introduced, oddly enough in one place as a simile to Satan, and in another to "the brandished sword of God." In the former of these places Milton makes a remarkable mistake by speaking of a comet "that fires the length of Ophiuchus huge in th' arctic sky." No part of Ophiuchus is thus situated; does he mean Draco? Dr. Orchard himself makes a mistake in p. 297, calling 1456 "the year in which the Turks obtained possession of Constantinople." The last chapter, on Milton's imaginative and descriptive astronomy, is, as might be expected, more full of passages from the great poem than any other, and appropriately closes a work which deserves, and will probably attain, a wide circulation.

W. T. LYNN.

OUR BOOK SHELF.

Cholera in Indian Cantonments, and how to deal with it. By E. H. Hankin, M.A. Pp. iv + 103. (Allahabad: *Pioneer* Press. Cambridge: Deighton, Bell, and Co., 1895.)

THE knowledge of the cholera microbe, gained during the past few years, is applied in this little volume in formulating directions for the prevention of the disease. The author has had exceptional opportunities of studying cholera outbreaks in India; and his experience in investigating sources of infection, renders the practical precautions he describes as necessary to prevent the spread of the disease in Cantonments, of great value to Cantonment magistrates, medical officers, and others interested in the question. Before dealing with the practical hints for the prevention of cholera, Mr. Hankin gives a brief account of the properties of the cholera microbe, which may be summarised as follows: (1) The cholera microbe when outside the human body, so far as is known, only lives and reproduces in water; (2) it is so small that it cannot be removed by filtration through ordinary domestic filters; (3) it is easily and rapidly destroyed by boiling; (4) it is rapidly destroyed by drying; (5) it is readily killed by acids; (6) it varies in virulence; (7) laboratory experiments show that its growth is favoured by the presence of traces of common salt and of nitrates in its culture fluids.

In a chapter on cholera epidemics, irregular and otherwise, it is shown that infection is caused by swallowing the microbe either in food or water; hence the precautions laid down are mainly concerned with the means for preventing the access of the microbe to the food and water supply, and with easy methods of disinfection. The instructions given are such as can readily be carried out, and though they are not so elaborate as the regula-

tions published by the German Government in the year 1893, an abridged translation of which forms an appendix to Mr. Hankin's book, they are sufficient for the purpose, and are better adapted to Indian Cantonments.

Chemical Experiments, General and Analytical. By R. P. Williams. Pp. 110. (Boston, U.S.A., and London: Ginn and Co., 1895.)

This is a practical, and, in some respects, an admirable, manual for chemical laboratories. The experiments described in the first half of the book instruct in metric measurements, glass manipulation, physical changes, chemical changes, and the preparation, properties and tests for the non-metallic elements and of the most important gaseous compounds. This part of the volume furnishes a good introductory course of practical chemistry. In the second part, the general and analytical reactions for metals are tabulated, the method adopted being to take each metal of a group separately and give the analytical reactions for it, and afterwards to treat the group in the same way. As a whole, the book should prove of service to students of analytical chemistry. Two features possessed by it offend the eye: one is the reformed chemical orthography, such as sulfuric for sulphuric, oxids for oxides, iodin for iodine, and so on; the other is the use of nearly sixty abbreviations, as, for instance, in the following sentences.

"Put into a t.t. or e.d. a thin piece of Cu, say $1^{qcm.}$ add 10 or 20 drops HNO_3" (p. 19).

"Put into a gen. (rec. or t.t.) 5^{g} FeS, $10^{c.c.}$ H_2O, and $5^{c.c.}$ HCl (or H_2SO_4)" (p. 42).

"Arrange the app. with inverted recs. as for the hydrogen exp." (p. 35).

Something may perhaps be said for the free use of abbreviations of this character by trained chemists, but their introduction in a book for young students is apt to lead to slovenly habits.

Traité de mécanique générale. Par H. Resal. Deuxième édition, entièrement refondue. Tome premier et deuxième. Pp. 166 and 300. (Paris: Gauthier-Villars, 1895.)

In editing the first two volumes of the seven volumes which form M. Resal's "Traité de mécanique," the author has seized the opportunity of completing certain subjects in the seventh volume, to which he directs attention in his preface. The scope of this treatise is so very great, covering all the ground of modern Theoretical and Applied Mechanics, that the author is debarred from entering into much detail. Thus, for instance, such a large subject as Hydrodynamics, including Hydraulics and Sound, is polished off in about sixty pages.

The work is obviously intended to serve as a text-book n Government technical schools, in which the amount of various knowledge required from a student is so great that he does not allow himself to become interested in details. G.

Modern Stone-Cutting and Masonry. By John S. Siebert, C.E., and F. C. Biggin, B.S. Pp. v + 47. (New York: John Wiley and Sons. London: Chapman and Hall, Limited, 1896.)

The arts of stone-cutting and masonry, and their applications in engineering and architectural practice in the United States, are briefly treated in this book, with special reference to the making of working drawings. The information given is of a thoroughly practical nature, and the fourteen plates, containing drawings of various forms of buttresses and arches, furnish useful examples of actual masonry work. The book will be found serviceable and instructive to students of the section of engineering and architecture described in it.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Two Brilliant Meteors.

On April 8 and 12, fine meteors were observed at various places in England.

The first of these appeared at about 8h. 21m. (April 8), and descriptions of its apparent path have reached me from Croydon, Kenley and Sutton in Surrey, also from Bridgwater, Reading and Crowthorne.

At Croydon the meteor was described by Mr. Salmon as a beautiful one, passing from Arcturus to near α Cassiopeiæ. Duration, ten seconds. The nucleus divided into two fragments. At Kenley Mr. Evershed noticed the meteor travelling from Arcturus to β Cassiopeiæ. It finally broke into fragments after a duration of five or six seconds. At first it was not brighter than a second magnitude star, but increased rapidly, so that at the end of its flight it was many times brighter than Venus. Mr. Bawtree, of Sutton, describes the path as from near β Draconis to β Cassiopeiæ, and estimated the duration as six to ten seconds. Mr. Corder, at Bridgwater, saw the meteor through trees, and at a low altitude, so that it did not appear to him brighter than Vega. Towards the end the nucleus divided into three. Its path was from $225^\circ + 15^\circ$ to $260^\circ + 40^\circ$, and duration six seconds. Mr. Saunder, at Crowthorne, Berks, says the meteor was several times as bright as Jupiter, and that before its disappearance the head was in several distinct pieces. Its path was from δ Boötis to near β Cephei. Mr. Davis, at Reading, describes the meteor as being equal to Venus, and passing in twelve seconds from near Arcturus to the point $340^\circ + 57^\circ$. It broke up into fragments at the end.

The second meteor appeared on April 12 at 8h. 6m., and I have accounts of it from Greenwich, Wellingborough, Bridgwater, Stokesay, Nottingham, West Malvern, Southport, Slough, Dunstable, Lochwinnoch, Renfrewshire, and several other places. At Greenwich, Mr. Dyson estimated the meteor as four times as bright as Jupiter, and describes the end part of its flight as being about 15° below the pole from W. to E. Mr. Tatman, of Wellingborough, says the meteor passed from N.E. to S.E., and occupied 12 seconds in its transit, ultimately disappearing behind a dark cloud. At Bridgwater the meteor moved from about 30° altitude in N. to 15° in N.E., and appeared to be about the size of the moon in one of her quarters. Mr. C. E. Clough, at Southport, says the meteor fell vertically about 15° to the right of Arcturus. In brightness it was estimated to equal two full moons. When first seen it was about 60° high, and it disappeared at an altitude of about 10° or 15°. At Nottingham, Mr. J. T. Wood says the meteor crossed the zenith, and was last seen near δ Virginis. It was ten times as bright as Jupiter. At Oxford, Mr. Robinson gives the time as 8h. 6m., and describes its course as from $7\frac{1}{2}^\circ + 60^\circ$ to $257\frac{1}{2}^\circ + 37^\circ$. Its duration was six seconds, and the meteor equalled and probably excelled Jupiter in brilliancy. At Lochwinnoch, Renfrewshire, Mr. P. Dewar noticed the meteor at 8h. 4½m., and says its motion appeared slow, lasting for four or five seconds. Its direction was from S.E. to E., and it disappeared near the horizon. At Coalbrookdale, Shropshire, the object was seen to come from the west, travel to N.E. and be lost towards E. The observations at Stokesay and West Malvern appear in NATURE of April 23, p. 581. I have a few other descriptions, and they are in satisfactory agreement.

The real paths of the two meteors appear to have been as follows:—

	April 8, 8h. 21m.	April 12, 8h. 6m.
Height at appearance	65 miles	118 miles
Position over	Straits of Dover	Formby, Lancashire
Height at disappearance ...	38 miles	34 miles
Position over	S. border Leicestershire	Doddington, Camb.
Length of observed path ..	161 miles	177 miles
Velocity per second	20 miles	19 miles
Earth point	Irish Sea	Woodbridge, Suffolk.
Radiant point	$204^\circ - 9^\circ$	$50 + 42$
Inclination of meteor's descent	9°	31

The meteor of April 8 was directed from a radiant in the eastern limits of Virgo, and not far from Spica. A fireball was seen on March 16 last, which was probably from the same radiant, as the paths converge on the point $205^\circ - 18^\circ$. This region is the centre from which many fireballs and ordinary shooting stars are directed in April and other months, as the following table will prove:—

Radiant point	Date.	Description	Observer or authority
210 − 6	January 5-11, 1870	Meteor shower	Tupman
205 − 8	January 20-22, 1877	,, ,,	Denning
200 − 5	January 20—Feb. 3, 1896	,, ,,	Herschel
204 − 10	January 21—Feb. 23, 1869	,, ,,	Denning from Tupman's obs.
202 − 9	February 13, 1869	,, ,,	Tupman
210 − 13	February 15-21, 1877	,, ,,	Denning
200 − 10	March 2-3, 1870	,, ,,	Tupman
205 − 18	March 16, 1896	Fireball	Denning
204 − 10	March 23, 1895	Meteor shower	Denning
204 − 8	March 31—April 12, 1872	,, ,,	Denning from Italian obs.
210 − 10	April 7-16, 1877	,, ,,	Denning
216 − 10	April 11, 1871	Fireball	Niessl
206 − 8	April 12-26, 1879	Meteor shower	Sawyer
210 − 7	April 1877	,, ,,	Corder
209 − 3	April 1874	,, ,,	Denning
209 − 9	April 1896	,, ,,	Herschel
198 − 8	April 18, 1841	,, ,,	Forshey
214 − 13	April 21, 1887	Fireball	Niessl
218 − 5	April 21, 1889	Bright meteor	Denning
210 − 9	April 19-23	Radiant 10 fireballs	,,
207 − 7	April 22, 1876	Meteor shower	,,
206 − 9	April 27, 1851	Fireball	Niessl
209 − 8	May 3-15, 1872	Meteor shower	Denning from Italian obs.
214 − 7	May 12, 1878	Fireball	Herschel
214 − 7	May 29, 1889	,,	Denning
217 − 6	July 7, 1895	,,	,,

The mean of the twenty-six positions is $209^\circ - 9^\circ$.

The fireball of April 12, 1896, came from a radiant in the N.W. sky at $50^\circ + 42^\circ$. The large meteor of April 22, 1894, had a similar radiant (*Observatory*, June, 1894), and the same may be said of the fireball of March 9, 1875.

Bristol, April 27. W. F. DENNING.

Becquerel and Lippmann's Colour Photographs.

I WISH to raise a point in connection with the optics of photochromy, which was not touched upon at the recent discussion at the Royal Society. The photochromatic spectra produced by the earlier workers, and especially by E. Becquerel about 1850, have long been known and have always appeared to be very mysterious to those who have repeated the experiments. When Prof. Lippmann's success with the interferential method was made known some five or six years ago, and his first results exhibited in this country, many of those who were acquainted with the previous methods of producing coloured spectra by direct impression came to the conclusion that all the earlier workers had unconsciously been producing the Lippmann effect. This supposition was not unreasonable. In Becquerel's method, for instance, which gave the most brilliant effects, the sensitive film of violet chloride is produced on a surface of metallic silver, and is thus backed by the necessary reflecting surface. Even when the colour sensitive chloride is on paper, as in the still earlier experiments of Robert Hunt and Sir John Herschel, it is not unreasonable to suppose that the bounding surface of the paper and silver haloid reflects sufficiently well to produce the necessary interference. At the discussion following Prof. Lippmann's paper, Lord Rayleigh raised the question whether the earlier and later results were not due to the same cause, but there seemed to be an impression that the Becquerel and Lippmann effects were produced by different causes. For my own part, I am bound to confess that the reasons assigned for arriving at this decision still appear to be inconclusive. The main points which have been allowed to prevail are that the Becquerel photographs cannot be fixed, that they appear of the same colour at whatever angle they are viewed, and that they appear of the same colour by transmitted and by reflected light. The fact that these photographs cannot be fixed is easily explained if we bear in mind that the silver salt, is not embedded in a vehicle, as in Lippmann's process, and that there is consequently nothing to hold the laminæ apart at the correct intervals when the fixing solution has done its work. The other points are less easy to explain; but it may be suggested that the difference is here due to the earlier experimenters having used coarse-grained films, in which the silver haloid particles are sufficiently large to *scatter* the colours produced in the film by the laminated structure of the alternating planes of decomposition and no decomposition. The question is a purely physical one, and may be put into the following form:—If the Lippmann effect is produced in a coarse-grained instead of in a transparent film, would not the Becquerel results be obtained? If physicists can answer this in the affirmative, the difficulty of supposing that similar results can be obtained by totally different causes would disappear.

R. MELDOLA.

Aquatic Hymenoptera.

UNDER the title "On Two Aquatic Hymenoptera, one of which uses its Wings in Swimming," Sir John Lubbock, Bart., read a paper before the Linnean Society, May 7, 1863, therein describing two most extraordinary insects, which he named *Polynema natans* and *Prestwichia aquatica*.

Last year I had the good fortune to obtain a large number of both sexes of the first named, which, after most critical microscopic examination, I identified as belonging to Haliday's *Caraphractus cinctus*, the unique characteristic of the "*keeled* metathorax" placing the matter beyond a doubt. The late Prof. Riley, to whom I had the pleasure of showing specimens, fully confirmed my opinion, as also did Mr. Charles Waterhouse.

The life-history of any of these minute Hymenoptera is not worked out in one season—very far from it; and since last year I have steadily followed up the chain of facts, my efforts being again rewarded by finding this most exquisite Hymenopteron this season within twenty miles of London.

Encouraged by my success, I continued my search for some hours at a small pond, and at last captured two female specimens of the long-lost-sight-of *Prestwichia aquatica* (Lubbock), which has not been recorded since its first capture by Sir John Lubbock in 1862—thirty-four years ago!

The two specimens (and *I*) have scarcely taken any rest since their capture yesterday morning, May 4; but they have been constantly running or paddling *under* water, never once having been to the surface. When I first put them into the tank, they had the *greatest* difficulty in forcing their way through the film; but as soon as that was accomplished, they moved about with their legs, as propellers, far more rapidly than did *Caraphractus cinctus* with its wings.

I am looking forward to capturing the *male Prestwichia aquatica*, which has not yet been recorded by any entomologist.

21 Manor Gardens, Holloway, N. FRED. ENOCK.

Dalton's Atomic Theory.

IN the review of "A New View of the Origin of Dalton's Atomic Theory," published in your issue of April 16, your reviewer, in summing up the evidence as to the origin of the atomic theory, makes an omission of such importance that it cannot be allowed to pass unchallenged. He attaches great weight to Thomson's statement that in 1804 Dalton himself informed him "that the atomic theory first occurred to him during his investigations of olefiant gas and carburetted hydrogen gas." Now these researches, as pointed out by your reviewer, were begun in the summer of 1804, a date which is assigned to them by Dalton himself, and is confirmed by the entries in his laboratory note-books of the time; so that Thomson's statement amounts to saying that the atomic theory first occurred to Dalton in the *summer of 1804*. This conclusion appears to us to be entirely discredited by the fact that several detailed tables of atomic weights and lists of atomic symbols, which are dated *September 1803*, occur in Dalton's laboratory note-books, one of these tables being reproduced in facsimile at p. 28 of the work under review, but not referred to by your reviewer.

It must be remembered that Thomson's account of the origin of Dalton's theory was first published in his "History of Chemistry" (vol. ii. p. 291) in 1831, no less than twenty-seven years after his visit to Dalton had been paid. Moreover, in 1850, after the lapse of another nineteen years, he gave a second and totally different account of the origin of the same theory, saying it was founded on the analysis of protoxide and deutoxide of nitrogen (Henry, "Life of Dalton," p. 80).

THE AUTHORS.

THE question is whether Dalton was led to apply the Newtonian doctrine of atoms to the explanation of chemical

phenomena (1) by a consideration of the composition and properties of atmospheric air; or (2) in consequence of remarking the results of the analysis of certain pairs or series of chemical compounds, the composition of which illustrates the law of multiples.

The authors contend for the former view, and adduce the contents of the lecture note-book dated 1810; but these notes of lecture 17 contain evidence of confusion in the statements made by Dalton himself. In these notes he says (p. 14 of the book), "In order to reconcile or rather adapt this chemical theory of the atmosphere to the Newtonian doctrine of repulsive atoms or particulars, I set to work to combine my atoms upon paper," &c. (P. 15), "In 1801, I hit upon an hypothesis." This hypothesis relates to the mutual repulsion of gaseous particles. (P. 16), "Upon reconsidering this subject it occurred to me that I had never contemplated the effect of difference of size. . . . This idea occurred to me in 1805." (P. 17). The different sizes of the particles being once established, "a train of investigation was laid for determining the *number* and *weight* of all chemical and elementary principles which enter into any sort of combination one with another."

So that the atomic theory as applied to chemical combination took shape in Dalton's mind according to this version of the story in 1805. Yet according to another of the note-books, quoted p. 26, he was using symbols to express the atoms of elementary bodies in 1803. The authors notice this conflict of statement, but get rid of it by assuming 1805 to be a clerical error for 1803.

Thomson was probably wrong in attributing the origin of the atomic theory to the study of marsh gas and olefiant gas. But in his exposition of the Daltonian doctrine, prepared only a short time after his interview with Dalton, he illustrates the use of the atomic doctrine by reference to the oxides of nitrogen. This was in his third edition, published 1807. In his sixth edition he introduces the oxides of carbon as well as the oxides of nitrogen. Thomson, therefore, from the time of his interview with Dalton retained the impression that the genesis of the theory was intimately connected with the facts known to Dalton as to chemical combination in multiple proportions, though he was evidently not clear as to the particular case first considered. That it was the oxides of nitrogen which first attracted Dalton's attention is, however, probable from the fact that he refers to them in the following noteworthy passage which occurs in his paper on the atmosphere read at Manchester, November 12, 1802: "These facts clearly point out the theory of the process: the elements of oxygen may combine with a certain portion of nitrous gas, or with twice that portion, but with no intermediate quantity." The authors have succeeded in discrediting the story about marsh gas, but it still remains doubtful whether Dalton's recollections in 1810 of what occurred six or seven years before are more trustworthy than the impressions of Thomson received much earlier, when it is a question as to the order in which various considerations came before his mind in the long course of meditation which led to the adoption of his theory.

YOUR REVIEWER.

An Advance in Röntgen Photography.

SINCE my last communication I have been pursuing the study of the photography of the soft tissues in the living adult subject, and making attempts to see shadows of them on the fluorescent screen. In a previous communication I was able to state that I had accomplished these in the region of the neck, the tongue, hyoid bone, larynx, &c. Proceeding downwards, I have now photographed and seen shadows of the cardiac area. In the photograph the diaphragm is clearly indicated below; the pyriform shape of the cardiac area is well made out, the base downwards, apex upwards, and the right and left borders show the relationship to the spine and ribs.

JOHN MACINTYRE.

PROJECTS FOR ANTARCTIC EXPLORATION.

ON January 28, 1841, Captain James Clark Ross and his comrades on her Majesty's ships *Erebus* and *Terror*, saw for the first time the giant volcanoes, rising in latitude 78° 30′ S., which bear the names of the only vessels that ever sighted them.

Fifty-five years later we remain in possession of no more information regarding these regions than was brought home by the discoverer. This is a circumstance absolutely unique in the modern history of geography. During these fifty-five years the map of Africa has developed from a *carte blanche* into a well-ordered delineation of mountains, lakes and rivers, even towns and villages the names of which are household words. In the far North the limits of the unknown have been and are still being strenuously pushed back. It is only in the far South that the explorer's march has been stayed, and during the last ten or fifteen years the importance of securing a farther advance in this direction has been given expression to, with increasing frequency and emphasis, by the scientific men of all countries. The latest and most weighty statement on the subject was the resolution of the Sixth International Geographical Congress, drafted in London by the leading geographers of Europe, to this effect:

"That the Congress record its opinion that the exploration of the Antarctic regions is the greatest piece of geographical exploration still to be undertaken. That, in view of the additions to knowledge in almost every branch of science which would result from such a scientific exploration, the Congress recommends that the scientific societies throughout the world should urge, in whatever way seems to them most effective, that this work should be undertaken before the close of the century."

It is clear to all scientific men that, although the recent experimental trips of Scottish and Norwegian whalers to the Antarctic regions have led to some distinct advances in our knowledge, and have rightly occupied a good deal of attention, they leave the question of serious exploration untouched. In the absence of a real expedition, we must continue to eagerly utilise every scrap of information which may be obtained by any means; but such trifles are only of provisional value. The drowning man may, for want of other floats, catch at straws, but the least critical spectator of this proverbial tendency would not argue that a life-belt was therefore unnecessary.

Antarctic exploration, if newspaper reports are to be trusted, has been commenced by the American Dr. Cook, who accompanied Lieutenant Peary on one of his journeys in Greenland, and has now got together a small scientific party on board two little sailing vessels of only 100 tons, with which he hopes to penetrate to the coast of Graham's Land and winter there. Weddell, in 1823, succeeded in reaching 74° 15′ S., in that neighbourhood, one of his vessels being only 65 tons, so that small size does not necessarily mean failure. If Dr. Cook has experienced ice-navigators with him, he will probably be able to effect a landing and collect some useful information. His equipment, however, is, we fear, inadequate to the task he has undertaken, and much must not be expected from it.

A more serious effort is announced as almost ready. It is to be commenced in September this year, under a flag which we believe has not hitherto appeared in polar regions, that of Belgium. The proposed expedition is being arranged by Lieut. A. de Gerlache, of the Berlin Navy, under the auspices of the Royal Belgian Geographical Society, and the expenses, which are estimated at £10,000, are to be met by public subscription. It is said that a large proportion of the money has been promised, the Brussels municipality have voted a grant; but until the whole of the cost is guaranteed, it would be rash to look upon this or any other expedition as a settled affair. A strong scientific staff is intended to accompany the vessel, which will probably try to get south along the east coast of Graham's Land.

In Germany the enthusiasm for Antarctic exploration has been gradually rising, and a strong Committee was appointed at the Eleventh German Geographical Congress, held last year at Bremen, to organise an expedition.

Dr. Neumayer, of the German Marine Observatory at Hamburg, and Herr G. Albrecht, of Bremen, are the Presidents, and the Secretary is Dr. Lindeman, who for many years has, through his editorship of the *Geographische Blätter*, kept the German public fully informed concerning all polar matters. This Committee has recently issued a detailed plan and estimates of a great German expedition to be sent out, not by the Government, but by the nation.

The objects of the expedition are defined as being the study of the meteorological and magnetic conditions of the South Polar area, geodetic observations, zoological, botanical and geological collections, the study of Antarctic ice, and the exploration of the still untouched polar region. For these purposes a station, in which observers can winter, would be fitted up either on the Antarctic continent or on one of the neighbouring islands, and one ship would remain in the nearest safe harbour which could be found, while the second vessel should spend the winter in cruising round the Southern Ocean making oceanographical researches.

The point at which an effort should be made to break new ground within the Antarctic circle was carefully considered, and the region between 70° and 85° E., *i.e.* south of Kerguelen, was selected, for the excellent reason that no previous serious effort has been made south of the Indian Ocean. Special value is placed upon magnetic and meteorological observations at Kerguelen or McDonald Island, because these lie nearly equidistant between the great observatories of Cape Town and Melbourne to west and east, and at a corresponding distance from the observatory of Mauritius to the north.

The recent publication by Dr. Murray, in the *Transactions* of the Royal Society of Edinburgh, of a detailed account of the work of the *Challenger* in the neighbourhood of Kerguelen, with lists of all the species obtained by the collectors on board, will be of service in guiding the biological work of the expedition, while at the same time it furnishes a compact summary of all that is at present known of the marine life and deposits on the edge of the Antarctic.

The German expedition is intended to include two vessels of about 400 tons, no doubt of the type of steam whalers, each carrying four officers, a scientific staff of four, and a crew of twenty-two. The ships would be absent for about three years, and would spend two winters in the Antarctic regions. The total cost is estimated at 950,000 marks, or £47,500, and the German nation is appealed to to find this money, the report of the Committee as published in the *Verhandlungen* of the Berlin Geographical Society concluding:

"The leading Powers of the civilised world appear to be preparing to attempt the solution of the great problem of the geographical conditions of the Antarctic regions. The German nation, always a leader in the solution of geographical problems, cannot possibly lag behind in this contest, the less so because a great and successful voyage of discovery would largely increase the reputation of Germany on the seas, and bring the greatest honour to the German name."

Beside this patriotic sentiment, the practical outcome of which the scientific world and not Germany alone looks for with hope and confidence, we may place a remark from another continental scientific paper, which from the reported refusal of the British Government to consider a proposal for a national expedition, drew the not illogical conclusion that the whole strength of the British Navy had to be brought under requisition for the purpose of making a warlike display before the great Powers. The President of the Royal Geographical Society at a recent meeting observed that "never was there a more favourable opportunity than the present for our Government to demonstrate its confidence in its own naval resources, by detaching a small expedition for special service in Antarctic research." The country is always ready to applaud and support a movement for the honour of the flag and the popularisation of the navy. If a contest between the great Powers is called for by the unthinking of several nations, what contest could be better than friendly rivalry in the advancement of science by maritime exploration? Around the South pole there is room for many simultaneous expeditions. Ross from Britain, Wilkes from the United States, and Dumont D'Urville from France were together in Antarctic waters fifty-six years ago, and the scientific world would gladly hail the early repetition of such history.

The Antarctic Committee of the Royal Geographical Society having been warned that an appeal to Government is not likely to be favourably entertained, has not as yet come to a decision as to its future action. The agitation for a complete scientific expedition will certainly not be allowed to rest. The only want is money; and surely some means can be found to supply this. The necessary amount would never have been missed from the surplus recently at the command of the Chancellor of the Exchequer. If the 600,000 professional men of the British Islands were to subscribe half-a-crown each, the resulting £75,000 would suffice for a very valuable expedition. If a few of the largest daily papers were to start a popular shilling subscription, they might without expense to their proprietors confer a priceless boon on science, and stimulate a healthy excitement in the public. There surely remain in this country some men—at least one man—able to do for the South Polar region what Mr. Harmsworth is so generously doing for the North; and to induce such potential benefactors to make their names great in history should not be an insurmountable task. The last and greatest feat of exploration on our planet may still be done, and allow the nineteenth century to close on a *Terra Cognita*; and the doing of it may still be secured for our country. If the opportunity is not taken now, it may not occur again for us, and the inevitable enrichment of science will redound to the glory of some more far-sighted, more patriotic, and less selfish people. It is an error surprisingly common, and every day becoming more ludicrously erroneous, that only Englishmen are capable of great deeds of daring and perseverance. If we are to retain our pre-eminence in polar exploration, we shall have to fight for it, not with armoured ships costing a million pounds apiece, but with a few old wooden whalers that may be purchased, manned, and equipped for a three years' cruise for less than a tenth part of that sum. Nothing less than a well-equipped scientific expedition can be looked upon as sufficient for the purpose in view.

Mr. T. Gilbert Bowick, of 2 Savile Row, is, as mentioned in a recent number of NATURE, at present completing arrangements for securing a passage for a party of scientific men on a whaling expedition, which is expected to set out in the autumn of this year, and will endeavour to land the passengers near Cape Adare (lat. 71° 45′ S.) in November 1896, returning for them in December 1897. Mr. C. E. Borchgrevink, whose Antarctic voyage is described in NATURE (vol. lii. p. 375), is proposed as the leader of the scientific party, which is intended to include twelve members. The plan of work involves the exploration of the coast of South Victoria Land and shallow-water dredging from a small steamer, which will be left at the winter quarters. Most of the work will naturally consist of meteorological, biological and geological observations near the station at Cape Adare, but a *ski*-journey is projected over the ice-cap in the direction of the magnetic pole. This expedition will, we hope, be undertaken, and if a landing can be made and a station established, the results will be of great value; but such an expedition, useful as it must be, is not sufficient. The alternative seems to be to allow the German and Belgian expeditions the full glory of renewing

serious work in the Antarctic, or to equip an adequate British expedition to co-operate with them by conducting simultaneous observations on the other side of the unknown area. An expedition a few years hence would be much less serviceable, because the value of consecutive work is at most additive, while that of simultaneous work is as the square, or some higher power, of the numbers engaged.

For the first time a south-polar map on a good scale is now available, thanks to the enterprise of Herr von Haardt of Vienna, and his publisher Hölzel. It is on a polar projection, and the scale of 1 : 10000000, approximately 160 miles to one inch. A special feature is made of ice-conditions and ocean currents, and the tracks of all the important southern voyages are laid down. But the most impressive feature is the vast central blank wherein lie hitherto untouched gold-fields of scientific data. HUGH ROBERT MILL.

THE HEIGHT OF LUMINOUS CLOUDS.

IN the *Astronomischen Nachrichten* (No. 3347), Dr. O. Jesse gives a short condensed account of some of the main results that have been obtained from a discussion of all the observations made during the years 1889–91. The full discussion, entitled "Die leuchtenden Nachlwolken," will, however, soon appear in the Publications of the Konig. Sternewarte in Berlin.

Perhaps the most interesting part of this work is that which is based, for the most part, on a series of photographs taken simultaneously at Steglitz, at the Urania Observatory, at Nanen, and at Rathenow, which brings out prominently the fact that the height of these clouds since the beginning of the phenomenon in 1885 has remained for the most part constant. The first table given by Dr. Jesse shows to a remarkable degree this almost constant value obtained for the mean height of the clouds, the actual total mean value being 82·08 kilometres ± 0·009. The apparent constancy in the value thus obtained for the height of these luminous masses is even more surprising when it is remembered that the observations were not made exactly simultaneously, a task by no means easy, so that the fast movements of the clouds were liable to influence the results to some marked extent.

An examination of the facts, however, seems to indicate that if the observations had been made strictly simultaneously, then the zone in which these nocturnal masses move might be considered narrower than the observations have as yet indicated.

As the observations used in this discussion were made for the most part after midnight, the computed value of the height to which they extend can only be said to hold for those clouds observed at this time. As a matter of fact, however, the few observations made before midnight indicate also roughly the same elevation as above obtained, but the paucity of the observations renders impossible any degree of certainty being attached to the result obtained.

Another part of the investigation related to the question as to whether the apparent height of the clouds had always been the same as that deduced from the observations extending over the years 1889–91. To answer this, an examination of all the observations since 1885 was made to see whether the zenith distances for the same depression of the sun below the horizon had always been the same; which would necessarily be the case if the distance of the clouds from the earth's surface be assumed to be nearly always constant.

The observations employed were those made by Backhouse, of Sunderland, in Kissingen, and by Dr. Jesse himself in Steglitz. A condensed form of the table given by the latter is as follows:—

Number of observations.	Depression of sun below horizon.	Zenith distance of the clouds.	Probable error of observation.
	°	°	°
6	9·9	69·9	2·5
9	11·2	77·8	1·4
8	11·8	80·3	0·8
5	12·5	81·7	0·6
7	13·8	85·0	0·5

In the year 1889 the phenomenon of luminous clouds occurred on July 2, and was, fortunately, unusually bright, rendering it possible to make numerous accurate measures; these Dr. Jesse gives in the following table, and compares the results with those given above. The numbers are as follows:—

The Difference of the Zenith Differences on July 2, 1889, from those found in earlier Years.

Depression of sun below horizon.	Zenith distance of the highest point of the clouds. 1889, July 2.	From table.	Difference.	Variation in height for 1° error in measured Z.D.
°	°	°	°	km.
11·4	77·5	78·6	+1·1	6·4
11·7	79·1	79·9	+0·8	7·0
12·6	82·7	82·0	−0·7	8·2
12·9	83·1	82·7	−0·4	8·7

After allowing for the numerous sources of error which might account for some part of the large differences in the fourth column, Dr. Jesse adds that the magnitudes of these are such as to lead him to assume another source of explanation, namely, in the arrangement of the particles composing the clouds themselves. It is probable that the clouds vary very considerably in thickness vertically, which would also affect the differences to some extent; thus with decreasing zenith distances a largely increased impression on the measured zenith distance of the clouds would result.

Setting aside, however, the question of the origin of these small differences, the important main result of the investigations still remains intact, namely, that from the years 1885–91 the luminous clouds have always had nearly the same mean height, namely 82 kilometres, or about 51 miles. W. J. S. L.

THE BISHOP OF RIPON ON HUXLEY AND SCIENCE.

AT a meeting convened by the Leeds Philosophica and Literary Society, held a few days ago, a resolution was unanimously adopted appointing a Committee, consisting of the Mayor, the members of the Council of the Philosophical and Literary Society, and all others who volunteered to join, for the purpose of raising subscriptions in aid of the Huxley Memorial Fund. We rejoice at the formation of the Leeds Committee, but another cause of gladness is the address delivered by the Bishop of Ripon in support of the object for which the meeting was held. In no uncertain voice, Dr. Boyd Carpenter declared himself a supporter of the principles which guided Huxley's noble life, and proclaimed the righteousness of scientific truth. It is not often that dignitaries of the Church speak so boldly for science as Dr. Carpenter did at the Leeds meeting; and on this account, and also because many of our readers will be glad to see this public recognition of Huxley's integrity of thought and purpose, we gladly print a report, though an abridged one, of the address.

It would not be surprising to discover there are many in this meeting who would be prepared to point out one or two special and specific objections or difficulties they have felt in regard to Prof. Huxley's teaching. I think, however, you will agree with me that if we demand complete harmony of opinion, that stupid unanimity which betrays either ignorance or thoughtlessness, before we dare to speak in honour of any one whose

name has become great, we shall be in the position of those who have nobody to honour and no names to commemorate. I feel, therefore, though all may differ in some points from Prof. Huxley, there is not one of you who cannot with the most simple honesty of purpose take part in this meeting. I am here to do honour, as an English citizen, to the name of a great Englishman. We who belong to the English race are, I suppose, sometimes slightly jealous for its greatness in certain departments. We feel we are outstripped by our Teutonic neighbours in the pathways of investigation. We feel we are outstripped sometimes by our American neighbours in the process of invention. So that whenever we have a great man we might as well cherish him, and make the most of him. Nations are great from a variety of causes. Their geographical position contributes to their greatness; their fertility and wealth of soil, and their racial qualities play a large part in the conspicuous or obscure place they are able to fill on the platform of the world. But the element which constitutes the happiest source of national greatness is the possession of great men. Great men are in the nation what the highest peaks are in the geography of the land—they mark the high level to which the people are capable of attaining; they are fertilising water-sheds pouring out their rich stores on the great plains below them. A nation ought, therefore, to reverence its great men, for they are not merely the expression of national greatness, but high ideals producing a reaction, an enthusiasm, an ambition in the hearts of those who come after them. I think you will agree with me that Huxley was entitled to the epithet "great." He was a strong man among strong men. But it was not simply that he attained immense eminence in the walk of life to which he dedicated his powers, he possessed also an unique power of being able to look with a sympathetic and appreciative eye on other walks and realms of science than those which were peculiarly his own. And, therefore, he was able to take a larger outlook than many a man who, shut up in his laboratory, or working in the fields, or observing through his telescope, remained limited to one particular sphere of scientific work. And because Huxley possessed that power, he became what he himself humorously described, "a maid of all work, a gladiator-general for science." That position was a worthy and a useful one. He also possessed a marvellous gift of lucid exposition. He was able to make clear to the minds of those who were not scientific, thoughts and ideas which were eminently scientific. For these reasons we have a right to claim him as great—great in English life, great by virtue of his devotion to science, great by virtue of that wide appreciativeness he brought to bear upon it, and great in the power of being able to expound to others. I am here as a friend of knowledge, to do honour to one who enlarged its borders. I know there are many—though they are a diminishing quantity—who are disposed to look somewhat askance at the progress of science. In the history of the world it has been only too obvious that men through timidity have been afraid of the advance of knowledge, and it is not surprising to find that in the nineteenth century, with all its vaunted enlightenment, that spirit of timidity should have found expression. What men own and feel to be dear to them they cherish, and God forbid they should be hindered from cherishing it. Many a man looks on science very much in the same way as a woman who hugs her infant to her breast looks on the doctor who draws near, and in regard to whom she entertains some very unreal but still natural suspicion. When men hug to their bosom the faith which is dear to them, and which they feel to be bound up with their dearest hopes, one can quite understand their clinging more closely and looking apprehensively at the progress and advance of science. But men are beginning to understand that it cannot be in the nature of things that facts and truths will contradict those things which are nearest and dearest and most essential to men. And because we are men we claim it to be our privilege and our responsibility—I may almost say we claim it to be part and parcel of our probation in this world—to follow truth wherever it leads us. It is not, therefore, our duty to encourage a timidity which, if it were encouraged, can only lead to a fatal obscurantism. The progress of knowledge can only deepen and intensify our attachment to the things which are true, and things which are true cannot be out of harmony with the things round about us. The child, cherished and reluctantly parted with, is restored to us by his doctor healed and saved. Religious truth, in one sense, must always wait on scientific truth, and religious truth must often change its form at the bidding and on the information given it by scientific truth. I am not aware that in the history of scientific progress religion has ever lost; the precious jewels have always been restored to her in richer and nobler settings. Because I believe that the advancement of knowledge must be for the benefit of mankind, and could not in the long run be hostile to any of the things most precious to us, I stand here to-day to do honour to one who laboured in the cause of the advancement of knowledge, and did so much to make it the heritage of all people. And, lastly, I am here to do honour to one, for whose truthfulness of character I have the profoundest admiration. Prof. Huxley had what might almost be called an exaggerated tenacity for the thing which he believed to be true, and a reluctance to surrender the truthfulness of his spirit at the bidding of any man or any authority. "But," some may say, "he was antagonistic." This is not the place nor the occasion to speak of Prof. Huxley's attitude towards Christianity, or even towards faith; but it should be remembered that the antagonism of his spirit was far more called out by the unfortunate attitude adopted by some who professed and called themselves Christians than by anything in its (Christianity) own nature. The moral and lesson of it is perfectly clear. A man may show himself the antagonist of other men's errors and of other men's methods without in the least degree being hostile to those precious things on which the hearts of men were wont to repose. Prof. Huxley was not one to knock from under any cripple's arm the crutch that enabled him to walk. While he spoke the language which seemed to him to be justified against those whose methods he could not approve, his language at other times was of that childlike simplicity, that entire modesty, and that natural humility which belonged to all thinking, educated, and reasonable men. Because he seemed to be setting before the world, even when we did not agree with him, an example of simplicity and truthfulness of disposition, I am here to say I honour him. We all desire to honour one who, great in his powers, sought to extend the borders of knowledge, and thus to add to the comforts, the joys, and the assurances of life, and who showed a character so simple, steadfast and truthful.

NOTES.

Prof. Victor Meyer has been elected a corresponding member of the class of mathematics and physics of the Berlin Academy of Sciences.

Major P. A. MacMahon has been appointed to represent the London Mathematical Society at Lord Kelvin's jubilee commemoration in Glasgow.

The Bavarian Academy of Sciences at Munich has awarded the Liebig Gold Medal to Prof. F. Stohmann, Professor of Agricultural Chemistry in Leipzig University, and silver medals to Prof. B. Tollens, Professor of Agricultural Chemistry in Göttingen University, and Prof. P. Sorauer, of Berlin.

Mr. Frederic Ducane Godman, F.R.S., has been elected a Trustee of the British Museum.

The annual visitation of the Royal Observatory, Greenwich, will take place on Saturday, June 6.

Mr. G. Griffith left Liverpool for Toronto on Saturday, to make arrangements for the meeting of the British Association in 1897.

The exhibition galleries of the British Museum, Bloomsbury and of the British Museum (Natural History), Cromwell Road will be opened to the public on Sunday next from 2.30 to 7 p.m.; and will be opened on subsequent Sunday afternoons until further notice.

A special general meeting of the Geological Society will be held on Wednesday, May 20, in order to submit to the decision of the Fellows certain resolutions of the Council regarding a proposed transference of a portion of the Society's collections to the Trustees of the British Museum.

THE *Journal of Botany* states that Herr V. F. Brotherus, of Helsingfors, has just started on a botanical journey to Central Asia; he is going by way of Samarcand and Tashkend to Thian Shan, with the special purpose of investigating the mosses of the highlands of Issikkoul. The district is a new and promising one.

THE *Bulletin de la Société Botanique de France* records the death, on December 31, 1895, of M. R. P. Delavay, Roman Catholic missionary at Yunnan, at the age of sixty-two. Since his arrival in China in 1867, he had been a most industrious explorer of the flora of that country, having sent home to the Museum of Natural History in Paris more than 4000 species, nearly half of them new. According to the *Bulletin*, he described for the first time about fifty species of *Rhododendron* and *Pedicularis*, and about forty of *Primula* and *Gentiana*.

IN connection with next year's country meeting, to be held at Manchester, under the presidency of the Duke of York, the Royal Agricultural Society will offer two prizes of £100 and two prizes of £50 for self-moving vehicles for light and heavy loads. In both classes the self-moving vehicles are to be propelled exclusively by mechanical means. The points to which the special attention of the judges will be called are: due regard to the convenience of the public; ease of handling, with special reference to stopping, starting, and steering; economy in working, price, simplicity, strength of design, and weight of vehicle.

OUR American correspondent writes, under date May 1:—"Columbia College will send a band of naturalists, under the leadership of Prof. Bashford Dean, to explore Puget Sound this summer, leaving New York June 10. Three zoologists and one botanist will accompany the party. The deep-sea work will be done with the aid of the United States Fishery Commissioners' vessel *Albatross*. The region is almost unexplored, and important results are expected.—A delegation of prominent scientific men appeared before the Finance Committee of the United States Senate a few days ago, to urge legislation favouring the metric system, but were informed by Senator Sherman that it was probably too late to accomplish anything at this session of Congress."

THE provisional programme of the International Congress of Psychology, to be held in Munich on August 4 to 7, under the presidency of Prof. Dr. Stumpf, shows that there is likely to be a plethora of papers on all branches of the science of mind. Eminent psychologists from many parts of the world have sent papers, among those who have done so being M. E. Bértillon (Paris), Prof. Bernheim (Nancy), Dr. Alfred Binet (Paris), Prof. Delboeuf (Liège), Prof. H. Ebbinghaus (Breslau), Prof. Sigmund Exner (Vienna), Prof. Stanley Hall (Worcester, Mass.), Dr. E. Hering (Prague), Prof. P. Janet (Paris), Prof. Th. Lipps (Munich), Prof. W. Preyer (Wiesbaden), Prof. Th. Ribot (Paris), Prof. C. Richet (Paris), Prof. H. Sidgwick (Cambridge), Mr. G. H. Stout (Cambridge), Dr. Carl Stumpf (Berlin), and Dr. W. Wundt (Leipzig). Details as to the arrangements of the Congress, which promises to be truly international in membership, and broad in scope, may be obtained from the General Secretary, Dr. Frhr. von Schrenck-Notzing, Max Josephstr. 2 I, Munich.

WE learn from *Die Natur* of April 26, that the Imperial Russian Geographical Society has sent to the northern boundaries of Russia a large number of notices relating to the possible descent of Herr Andrée's polar balloon in Russian territory. The inhabitants are exhorted not to be frightened at the balloon, to treat the occupants, in case of need, with all respect, and to conduct them to the nearest Government authorities; the notice also states that any expenses incurred will be repaid. It is further requested that if the balloon be sighted, information should be given of the direction in which it was going. The document contains representations of the balloon, both in flying and falling conditions.

PROF. UGOLINO MOSSO (*Atti della R. Accad. dei Lincei*) describes a series of observations on human respiration at high altitudes, performed with the object of testing whether the quantity of carbonic acid exhaled in breathing is in any way affected by the rarefaction of the air. For this purpose a number of soldiers were tested in the course of an expedition on the slopes of Monte Rosa, and further experiments were made by the author on himself in an experimental chamber at the Physiological Institution of Turin. These observations prove that the quantity of CO_2 expired by a man at an altitude of 6400 metres, differs but slightly from that expired at 276 metres above the sea-level. Prof. Mosso subjected himself to pressures as low as 34 cm. of mercury without feeling any ill-effects, the oxygen present being still sufficient for purposes of respiration; but when the pressure was reduced to 30 cm., the author began to find his faculties impaired, and in one case felt a great want of breath. After about eleven or twelve minutes, he became incapable of making accurate observations, and the experiments had to be discontinued.

THE Kew Observatory Committee of the Royal Society have recently issued their Report for the year 1895. The Chairman of the Committee is Mr. F. Galton, and the Superintendent of the Observatory is Dr. C. Chree. At the suggestion of the Council of the Royal Society, the title of the Committee has been changed during the year: the change consists in the insertion of the word "observatory" and the omission of the word "incorporated." The magnetographs have been kept in constant operation throughout the year, but no very exceptional disturbances were registered during that period. An analysis of the declination and horizontal force results for selected "quiet days" during 1890-94 has been published in the Report of the British Association for last year. The self-recording meteorological instruments have also been in regular action during the year, and the observations have been transmitted, as usual, to the Meteorological Office. Sketches of sun-spots were made on 159 days, and the groups numbered according to Schwabe's method. Various experimental investigations have been carried on, in addition to the regular routine work, relating to fog, atmospheric electricity, platinum thermometry, &c. A sum of £100 was obtained from the Government Grant Committee for the purpose of making experiments on the behaviour of platinum thermometers; these are found to possess advantages even in dealing with some ordinary temperatures which require to be read at a distance from the spot where they are recorded. The total number of instruments verified, and of watches and chronometers rated, shows a considerable increase.

IT was not to be supposed that the astonishing announcement made by Jörgensen and Juhler as to the development of yeast cells from the *Aspergillus oryzæ* would go unchallenged; but it must, at any rate, be a satisfaction to these investigators that the inquiry has fallen into such skilled hands as those of Messrs. Klöcker and Schiönning, both assistants in the famous Carlsberg Laboratory. These gentlemen have repeated in every conceivable manner the experiments of Jörgensen and Juhler, and have even greatly extended the scope of their original observations; but in no single instance have they obtained any evidence of the development of yeast cells from moulds. It would appear that too much weight has been given to mere microscopical evidence, and not sufficient attention bestowed upon the acquisition of pure cultures. Perhaps the most interesting efforts to decide this knotty question were those investigations made with various fruits growing in a natural condition on trees,

investigations suggested by some early work of Pasteur, and also Chamberland, published in 1879. As is well known, moulds and yeasts are present side by side in large numbers on various fruits, such as plums, cherries, grapes, &c. ; and Messrs. Klöcker and Schiönning determined to prove, if possible, that their simultaneous presence is a mere coincidence, and not evidence of the development of yeast cells from moulds. Comparative examinations were therefore instituted of numerous fruits, some of which were simply gathered from the tree, whilst in other cases they were only examined after having been carefully excluded from the outside air for some time by enclosing a small fruit-bearing branch in a specially constructed glass case. Thus, for example, on none of the plums protected from the surrounding air could any yeast cells be discovered, although moulds were present in abundance, whilst on as many as 50 per cent. of those exposed to the air, yeast cells were found along with the moulds. Messrs. Klöcker and Schiönning contend that they offered the moulds the most natural and favourable opportunities for the production of yeast cells in these glass cases, which could be devised, but they failed in every case to make their appearance. Dr. Jörgensen himself, it is only fair to add, appears to be somewhat baffled by the nature of his observations, and in his most recent communication on the subject, frankly confesses that this elaboration of yeast cells from moulds must at present be regarded as a process in which chance appears to play an important part, and the circumstances attending which we are yet quite unable to master !

M. Moisson is reported (*Centr. Zeit. für Opt. u. Mech.*, xvii. 6) to have discovered a substance harder than the diamond in the form of a compound of carbon and boron, produced by heating boracic acid and carbon in an electric furnace at a temperature of 5000°. This compound is black and not unlike graphite in appearance, and it appears likely to supersede diamonds for boring rocks, cutting glass, and other industrial purposes. It will even cut diamonds without difficulty, and it can be produced in pieces of any required size.

According to Prof. J. C. Arthur, the popular idea that of the two seeds in the spikelet of wild oat, one germinates at once, and the other only after a year, has no foundation in fact. But this is true of the two seeds in the fruit of the "cockle-bur," *Xanthium canadense* and *strumarium*. The cause of the difference in the action of the two seeds appears to be constitutional and hereditary.

Only three species of Bears have hitherto been generally recognised by naturalists as occurring in North America, namely the Polar Bear, Black Bear of the Atlantic States, and Grizzly Bear of the Western States, though others have been proposed. In his recently issued "Preliminary Synopsis of the American Bears," Dr. C. Hart Merriam takes a very different view. Dr. Merriam raised the number of American Bears to no less than eleven, dividing those of the "grizzly" type (*Ursus*) into six species, and those of the "black" type (*Euarctos*) into four. Dr. Merriam's synopsis is illustrated by figures of the skulls of the different species.

M. E. A. Martel, President of the Speleological Society (Paris), has visited and surveyed the Mitchelstown Cavern in Ireland, and reports on it in the *Irish Naturalist* for April. Although discovered over sixty years ago, and well known to tourists, this cavern had never before been properly explored. Its chief peculiarity consists in its extensive ramifications, which in one part follow the jointing of the limestone so regularly that the plan looks like that of the streets of a town. The total length of the cave exceeds a mile and a quarter, so that it is probably the longest in the British Isles. Mr. Lyster Jameson furnishes a report on the living animals found in this and other Irish caves, which mostly fall into three categories—those inhabiting the entrance to the cave as a hiding-place, those that have accidentally been brought in, and those that form its normal fauna. The last consist of a spider and two *Collembola*, and are interesting as constituting the first true cave-fauna recorded in the British Isles. A description of these forms appeared in previous numbers of the *Irish Naturalist* and of *Spelunca*.

We have received from the Geological Survey of Norway a set of their Reports for the years 1893, 1894, and 1895, published by H. Aschehoug and Co., Christiania, at prices which bring them within the reach of every one who may be interested in the subjects of which they treat. The Reports are highly creditable to such a sparsely-peopled country as Norway, and to the Director of its Geological Survey, Dr. Hans Reusch, who seems to thoroughly appreciate the wants of his practical countrymen. As the country apparently possesses few organised public departments, the publications of its Geological Survey are comprehensive in their scope, covering questions of agriculture, forestry, climate, irrigation, soil, and orography, as well as of mining and geology. The economic aspects of the building-stone and mining industries are well considered and presented to the people for their deliberation and guidance, as well as the purely geological questions of stratigraphy and petrography. Palæontology, however, is conspicuous by its absence. One of the largest of the Reports deals with roofing-slates, flagstones, and with steatite as a building-stone. It is a pity that the vocabulary of the language is not rich enough to have different words for slate and schist (*Skifer* represents both); but our own language is equally faulty, or rather misapplied, when the word slate is used in referring to Stonesfield slate, as well as to that of Ballachulish or Llanberis.

In one of the Reports (No. 14) referred to in the foregoing note, there is an interesting communication by A. Helland, on the depths of the lakes in Jotunheim and Thelemark, as ascertained from soundings by himself and others ; but unfortunately all of them have been made in the line of the length of the lakes, none of them transversely, thereby missing a most important clue to the explanation of their origin. He gives longitudinal sections of four of the principal lakes in Jotunheim, but the irregularities in the bottoms are not favourable to the glacial erosion theory which he supports ; transverse sections would probably prove more instructive. Of the forty-two lakes mentioned, no less than twenty-three of them have their bottoms below sea-level. The following series of figures represents the number of feet below sea-level of the first twelve, viz. 1417, 1085, 715, 712, 593, 568, 528, 456, 456, 456, 361 and 190. The first is the Hornindals Vand, the surface of which is only 177 feet above sea-level, but the bottom is 1417 feet below it ; the second is the Mjösen Vand, the surface of which is 397 feet above, and bottom 1085 below, sea-level. The great depth below sea-level seems to militate against the theory that they were eroded by ice.

In the *Bulletin* of the Academy of Sciences of Cracow, Dr. L. Natanson contributes a long and elaborate communication on "The Laws of Irreversible Phenomena," and L. Birkenmayer describes a series of observations on the length of the seconds' pendulum in the neighbourhood of Cracow.

Prof. J. M. Coulter publishes, in the "Contributions from the United States National Herbarium," a revision of the North American species of *Echinocactus*, *Cereus*, and *Opuntia*. Fifty-two species are enumerated of the first genus, eighty-two of the second, and 101 of the third ; a good many of these are now described for the first time.

Mr. James Hornell, Director of the Jersey Biological Station, is issuing a series of Microscopical Botanical Sections,

similar to those in Zoology already published. The series will consist of twenty original photo-micrographs, accompanied by descriptive letter-press and illustrations. The subjects included in the part we have received comprise longitudinal and transverse sections through the underground bud of *Equisetum*, transverse sections through leaf-buds of the Elm and the Ash, cuticle of *Araucaria*, longitudinal section through node of Sycamore, longitudinal section through flower-bud of Peony, transverse section through fruit of Date-palm, transverse sections through flower-buds of *Iris* and *Lilium*.

MESSRS. MACMILLAN AND CO. will shortly publish "An Intermediate Course of Practical Physics," by Prof. Arthur Schuster, F.R.S., and Dr. C. H. Lees. The book will set forth the course of instruction in practical physics followed in Owens College during the last five years. The explanations having thus passed through the refining fire of a physical laboratory, have been cleared of all the obscurities which tease the intelligence of the average student. The book was primarily designed for use in preparing for the Intermediate B.Sc. and First M.B. examinations of the Victoria University, but the requirements of other Universities are so nearly identical that it will appeal to a much wider circle of students.

DURING the year 1895 the Albany Museum, Grahamstown, made excellent progress. From Dr. Schönland's report we gather that, owing to the large influx of specimens, the capacity of the museum is overtaxed, and the erection of a new building has become a matter of absolute necessity. The Government have therefore been asked for a sum to devote to this purpose, and, considering the value of the collections and the useful work the museum is doing, and can still more effectually perform in a suitable building, it is hoped that the grant desired will be regarded as a judicious outlay. Owing to the rapid growth and increasing value of the herbarium formed in connection with the museum, the Committee think it desirable that the expenses incurred by its management should be borne by a fund apart from the general revenue of the museum, and they have, therefore, asked the Government to grant an annual sum of £100 for this purpose. Dr. Schönland has been experimenting with formaline as a substitute for spirits of wine in preserving specimens. The results obtained have been satisfactory, but he is afraid to discard spirits of wine until he is sure that formic aldehyde is a perfectly stable compound, and will keep for a considerable length of time in the hot climate in which the museum is situated.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♀), two Sambur Deer (*Cervus aristotelis*, ♂ ♂) from India, presented by Mr. Greswolde-Williams; a Brown Capuchin (*Cebus fatuellus*) from Brazil, presented by Mrs. J. Hicks; three young Cheetahs (*Cynælurus jubatus*) from Somaliland, presented by Mr. Kenneth Foster; two West Indian Agoutis (*Dasyprocta cristata*) from the West Indies, presented by Mr. W. Weldon Symington; a Chinese Goose (*Anser cygnoides*, ♂) from China, presented by Mr. L. G. Leverson; a White-crested Cockatoo (*Cacatua cristata*) from Moluccas, presented by Mrs. Crofts; two Pennant's Parrakeets (*Platycercus pennanti*) from Australia, presented by Mr. Clifford Brooks; a Porose Crocodile (*Crocodilus porosus*) from Java, presented by Mr. A. W. Richmond; two Bennett's Wallabys (*Halmaturus bennetti*) from Australia, a Spotted Ichneumon (*Herpestes nepalensis*), two Hamadryads (*Ophiophagus elaps*) from India, deposited; an Entellus Monkey (*Semnopithecus entellus*, ♀) from India, a Great Anteater (*Myrmecophaga jubata*), two Picui Doves (*Columbula picui*) from South America, two Blue-headed Pigeons (*Starnœnas cyanocephala*) from Cuba, two Auriculated Doves (*Zenaida auriculata*) from Chili, four Cape Doves (*Œnas capensis*) from South Africa, two Crowned Pigeons (*Goura coronata*) from New Guinea, a Southern Fruit Pigeon (*Crocopus chlorogaster*) from India, a Nicobar Pigeon (*Calœnas nicobarica*) from the Indian Archipelago, purchased.

OUR ASTRONOMICAL COLUMN.

COMET SWIFT, 1896.—The following is Dr. Schorr's ephemeris for Berlin midnight (*Ast. Nach.*, 3349).

	R.A. h. m. s.	Decl. ° ′	Brightness.
May 14	1 30 19	+67 33·9	0·26
16	1 15 49	68 38·1	
18	1 1 20	69 31·9	0·20
20	0 46 52	70 16·9	
22	0 32 32	70 54·3	0·16
24	0 18 19	71 25·1	
26	0 4 14	71 50·3	0·12
28	23 50 16	72 10·5	
30	23 36 28	+72 26·3	0·10

The path of the comet lies in the northern part of Cassiopeiæ until May 25, when it passes into Cepheus.

A PHOTOGRAPHIC TRANSIT CIRCLE.—Many attempts have been made to replace the observer of star transits by a photographic plate; but as most of them require the plate to register star-trails, it is impossible in this way to record the fainter stars. Dr. H. C. Russell has recently proposed another method, which he believes will be capable of giving star positions with much greater accuracy than is possible with the existing transit circles, and is at the same time good for the fainter stars. The instrument is virtually a photographic telescope of thirteen inches aperture, mounted alongside a visual telescope in a rectangular box, which turns on trunnions within a polar axis of the "English" form. An electrically-controlled driving clock, and circles for declination and right ascension complete the instrument. On the scale suggested the circles may be large ones, so that declinations may be read by microscopes to 0″·1 and right ascensions to 0·01 sec. The polar axis would be adjusted by the familiar processes, and the instrument would be collimated like an ordinary transit circle; the line of collimation of the star camera must also be made parallel to that of the telescope. The telescope would be set on the desired star before the meridian, and the star would be constantly kept on the cross wire while the plate was being exposed; meanwhile the R.A. would be read off by a second observer noting the times at which the divisions of the circle pass a fixed microscope, the relation of each division to the meridian being very accurately determined. A third observer would read the declination circle. The instrument would next be reversed in the polar axis, and the observation repeated. If there were no collimation errors or flexure due to the position of the telescope the photographic images of the star would be superposed, and if they are not, the point midway between the spots may be assumed to be the mean of the unknown errors. There would of course be two images of any stars, except the guide star, that might be in the photographic field, and their positions relative to the guide star would be determined by measurement of the photograph. The advantages specially claimed are (1) the observation does not depend upon a flying shot at the bisection of a stellar image; (2) at least a partial elimination of unknown errors is effected; (3) the determination of R.A.'s with equal and extreme accuracy for stars in all declinations.

MR. TEBBUTT'S OBSERVATORY.—The report for 1895, which we have just received from Mr. Tebbutt, of Windsor, N.S.W., is a splendid illustration of what can be accomplished almost single-handed by an enthusiastic astronomer. Not less than 957 transits of stars were observed during the year, and this in addition to a varied series of other observations. A large number of occultations of stars was observed, and what may be regarded as a feat in this class of work was accomplished on August 29, when both phases of the occultation of the fifth magnitude star B.A.C. 6127 were observed in full sunlight. The micrometric work includes numerous measures of the positions of the minor planets Hebe and Ceres, and of seventeen double stars which are of peculiar interest. Jupiter's satellites and certain variable stars also received attention, and the various meteorological phenomena were recorded. Eleven papers on the results of the astronomical work were published during the year.

THE ROYAL SOCIETY CONVERSAZIONE.

Few conversaziones of the Royal Society have exceeded in interest the one held on Wednesday of last week. Many of the exhibits were very striking, while all of them presented novel features. Physical science predominated, and Röntgen photography attracted a large share of attention throughout the evening. Mr. A. A. C. Swinton had an elaborate exhibit to illustrate experimentally the production of Röntgen rays, and the visible and photographic effects produced by them. By means of several binocular cryptoscopes, all who so desired were able to see shadow pictures of the bones in the living body, and of objects enclosed in opaque boxes, while Röntgen photographs of the hands of many persons were taken during the evening.

Mr. Herbert Jackson's demonstration of the use of phosphorescent materials in rendering Röntgen rays visible, brought out the supremacy of potassium platino-cyanide as the salt for phosphorescent screens. The tube used to produce the rays was a slight modification (described in the *Proceedings* of the Chemical Society) of a tube originally introduced by Mr. Crookes to illustrate the heating effect of kathode rays. These are brought to a focus at the centre of curvature of the concave kathode, whence they proceed in nearly a straight line to a platinum plate, from the surface of which they are apparently scattered in all directions. The rays penetrating the glass were caused to fall upon phosphorescent bodies and were rendered visible, thus showing the different intensities of response of these bodies to such rays. By means of a large phosphorescent screen covered with platino-cyanide of potassium, all the effects seen individually with a cryptoscope were viewed by a number of people at the same time.

Mr. Sydney Rowland exhibited a series of "skiagrams" illustrating the applications of the "new photography" to medical and surgical diagnosis. The following analysis, based on a record of some fifty cases, is useful as showing the branches of surgery in which the new process will probably be found of most use. About 20 per cent. of these include the discovery and location of foreign bodies, needles, bullets, &c., lodged in soft tissues, and in one case a coin lodged in the intestine, which caused troublesome symptoms. In one of these cases two previous operations had been fruitlessly performed. 15 per cent. of the cases were instances of pathological conditions of the elbow-joint of more or less obscurity, on which new and unexpected light was thrown by the diagnosis thus obtained. In 10 per cent. of the cases the object in view was the determination of the extent and distribution of tuberculous lesions in bone. Various ankyloses and deformities of the bones and joints of the extremities have made up the remainder of the cases.

A self-testing resistance box and bridge were exhibited by Mr. E. H. Griffiths, F.R.S. This apparatus presented many novel features, the chief advantages being as follows:—(1) The observer can (without use of standards, &c.) ascertain accurately, and quickly, the comparative errors of all the coils, including those in the ratio-arms. (2) An exact calibration of the bridge wire can be made by means of the box itself. (3) The temperature of the coils can be accurately determined. (4) The resistance of leads to any object is self-eliminated. (5) Resistances from 0·00001 ohm to 10^5 ohms can be directly read by a null method, without observation of galvanometer swings. (6) All coils after adjustment have been heated to a red heat, and are thus very free from strain, &c. (7) There are special arrangements for securing constancy of all plug contacts, &c.

A resistance box, standard coils, and wire bridge were exhibited by Mr. F. W. Burstall. The resistance box was of the dial pattern, wound in bare platinum silver wire on strips of mica, the wire being immersed in pure mineral oil; there were five dials, ranging from $\frac{1}{10}$ ohm to 1000 ohms, and four pairs of proportional arms. The four standard coils were of similar forms, but were intended to be used with mercury cups. In conjunction with Mr. H. R. J. Burstall, the same exhibitor showed bare wire resistance thermometers for use in vessels under high pressure. The measuring wire was wound on mica plates carried by slender columns from a metallic plug which was screwed into the vessel. The change of resistance was measured by comparing the drop of E.M.F. over the measuring wire, with the drop over a standard coil put in series with it and a battery. A thermometer was exhibited which had been in a steam superheater for more than a week continuously, at a pressure of 160 lb. per square inch. Both these exhibits should prove of great assistance in electrical and thermometric measurements.

New apparatus for measuring the magnetic permeability of iron or steel was shown by Prof. Ewing, F.R.S. The apparatus allows measurements of permeability to be made with samples in the form of short rods, and greatly simplifies the process. It acts by making a magnetic comparison between the rod to be tested and a standard rod, the magnetic qualities of which have been determined beforehand. The magnetic detector, which shows when the two rods have the same induction, consists of a compass needle placed in a gap in an iron bar joining the two yokes. From its analogy to the Wheatstone Bridge, the author proposes to call the instrument a Permeability Bridge. It forms a companion instrument to the hysteresis tester exhibited last year.

A flint glass prism of nine inches aperture and 45° refracting angle was exhibited by Mr. J. Norman Lockyer, C.B., F.R.S. The prism has been constructed by the Brothers Henry, of the Paris Observatory, and will be used as an objective prism for photographing the spectra of stars. Mr. Lockyer also showed the following:—Photograph showing positions of coronal spectrum rings in the total eclipse of the sun, April 16, 1893. The original negative was taken by Mr. Fowler, at Fundium, West Africa, with the 6-inch prismatic camera near the middle of totality, with an exposure of forty seconds. In addition to the images of a number of prominences, there were portions of rings representing the radiation spectrum of the corona. The brightest of the rings corresponds to the well-known corona line 1474 K, but the others have not been previously photographed. All the rings are most intense in the brightest coronal regions, near the sun's equator.—Photographic spectra of α Cygni, γ Cygni, and Arcturus. The photographs were taken at South Kensington with a 6-inch objective prism of 45°, and illustrated the difference between stars of increasing and stars of decreasing temperature. Arcturus is a cooling star, almost identical with the sun, while α Cygni differs very widely from the sun and is getting hotter. The spectrum of γ Cygni, like that of Arcturus, consists of a very large number of lines, but as many of the more prominent lines agree with those of α Cygni, and are absent from the solar spectrum, this star must be classed with those of increasing temperature.—Photographs showing the spectra of helium and gas X in relation to the spectra of Orion stars. The lines of the two gases were arranged in the series deduced by Messrs. Runge and Paschen, and their distributions in the spectra of Bellatrix, Rigel, δ Orionis, and Spica were shown.—Photographic map of the spectra of metals of the iron group. The map extended from wave-length 3900 to 5900, and included the spectra of iron, manganese, cobalt, nickel, chromium, and uranium, as shown at the temperature of the electric arc. Rowland's map of the solar spectrum formed the term of comparison, so that the wave-lengths of the lines could be read off directly from the map.

Mr. F. McClean, F.R.S., exhibited photographs of the spectra of twenty-three characteristic helium stars. These stars correspond to Class I.*a* of Lockyer (*Phil. Trans.*, December, 1892), who further attributed their spectrum to helium (*Proc. Roy. Soc.*, May 9, 1895). The hydrogen and helium were indicated below the scale of wave-lengths. The enlargement was 8½ times the original negatives. Mr. McClean also showed photographs of the spectra of six stars of the third magnitude, illustrating the transitions from type to type.

Another spectroscopic exhibit was by Prof. Hartley, F.R.S., whose subject was, however, terrestrial. He showed a series of photographed spectra illustrating an investigation of the Bessemer flame, as seen at the North Eastern Steel Co.'s Works, at Middlesbrough-on-Tees, in which the presence of the rare element gallium was recognised by a single line in its spectrum, and separated from both the metal and the ore of the district.

A remarkable exhibit, by Mr. Joseph Goold, consisted of steel tuning-bars and synchronising sound-generators. The new synchronising sound-generator was a vibrating rubber having the pitch or vibration-period of the note to be elicited. The separate partial-tones were thus developed singly with remarkable power and sweetness. These appliances have already led to the further discovery of *vibration-axes and -vortices*, examples of which were exhibited.

The rapid photographic printing machines, exhibited by Mr.

W. Friese Greene, turned out prints at a rate almost beyond belief. The machines are for the production of prints wholly or partly by photography, and their chief object is to effect a very rapid production of copies adapted for use as illustrated supplements, newspapers or magazines, or for other purposes where a large number of copies of the same picture, design, or other objects are required. A roll of rapid bromide paper was fed in at one end of each machine, and finished prints were turned out at the other end at the rate of two or three thousand an hour. Mr. Greene also showed a new type-setting machine dispensing with movable types.

Instantaneous photographs of splashes were shown by Prof. Worthington, F.R.S., and Mr. R. S. Cole. These photographs were taken each with an electric spark giving an exposure of less than 3 millionths of a second (see NATURE, vol. l. p. 222.) The spark could be so timed as to pick out any desired stage of the splash within limits of error not exceeding, as a rule, about 2-thousandths of a second. In this way the progress of a great variety of splashes has been followed in minute detail. Specially interesting were those which illustrated the formation of a bubble, and those which showed how the nature of the disturbance produced by the entry of a solid sphere depended on the condition of its surface.

By means of the colour patch apparatus exhibited by Captain Abney, C.B., F.R.S., it becomes possible to throw on a screen, or on a photographic plate, the image of a luminous object in monochromatic light. An image is first formed on the face of a prism or grating by means of a lens of proper focal length, placed close to the slit of the spectroscope. The spectrum is formed in the usual way, and the colour in which the image of the object is to be formed is allowed to pass through a slit placed in the spectrum. A second lens placed close to this slit forms the image in monochromatic light of the image on the prism or grating on a screen or photographic plate.

Prof. Roberts-Austen, C.B., F.R.S., showed his interesting modifications of an experiment of M. Charles Margot. A wire of aluminium was raised, by a current of 30 amperes, to a temperature far above the melting point of aluminium, but a film of oxide on its surface prevented the wire from breaking. The molten wire through which a current was passing, could then be attracted by a magnet.

On behalf of Mr. Carl Zeiss, new portable binocular field-glasses and stereo-telescopes were exhibited. The objects of the new types are (1) to obtain a considerably larger field than that possessed by a Galilean telescope of similar magnifying power: (2) to enhance the stereoscopic effect of the images formed, by placing the object-glasses further apart than the eye-pieces. These objects were attained by prisms and astronomical oculars. The rays passing from the object-glass to the eyepiece undergo four reflections at the surfaces of the prisms, and emerge from the last prism with undiminished intensity. The interposition of the prisms serves to erect the inverted image formed by the object-glass, and, at the same time, to displace the axis of the eyepiece with respect to that of the object-glass, the amount of this displacement being variable within wide limits.

Mr. F. E. Ives had on view his stereoscopic photo-chromoscope. The photo-chromoscope camera makes, at a single exposure on a commercial photographic sensitive plate, three pairs of images, which by differences in their light and shade constitute a record of everything that excites vision in the two eyes. The stereoscopic photo-chromoscope translates this record to the eyes, so that the object photographed appears to be seen through it.

The composite archer's bow, its structure and affinities, was the subject of an exhibit by Mr. Henry Balfour. Archers' bows of composite construction, of wood or horn, or both, overlaid with a "backing" or reinforcement of animal sinews, were shown. There were complete bows from North-west America, Japan, Corea, Manchuria, China, North India, &c., a composite cross-bow from Germany, and an unique specimen of composite bow from a tomb of the twenty-sixth dynasty, Thebes, Egypt. A map and diagram showing the distribution and affinities of the various types of composite bows were also exhibited.

A bifilar pendulum in action was exhibited by the Cambridge Scientific Instrument Company. This instrument was designed by Mr. Horace Darwin for observing and recording slow tilts and pulsations of the earth's crust, by whatever cause they may be produced, and is a modification of that used by the Messrs. Darwin in 1881, at the suggestion of Lord Kelvin. It is possible to observe with this pendulum a tilt of less than $\frac{1}{350}$ of a second, an angle less than that subtended by a line an inch long placed at a distance of a thousand miles, as was shown by the experiments made at Birmingham by Dr. Charles Davison.

The results of experiments on steel gas cylinders were shown by the Gas Cylinder Committee, lately nominated at the request of the Home Office. These showed (1) the danger of using hard or unannealed steel for gas cylinders; (2) the extraordinary amount of violent ill-treatment to which a good soft annealed cylinder may be subjected without destruction, even when charged to 120 atmospheres; (3) the effect of very great internal pressure steadily applied, in this case due to the expansion of liquefied ammonia gas which completely filled the cylinder when cold; (4) the violently destructive character of the explosion of mixed gases under pressure which no practicable cylinder can withstand.

Portable apparatus for gas-testing in electric culverts was shown by Prof. Clowes. A standard hydrogen flame, fed from a small steel cylinder of the compressed gas, is enclosed in a brass vessel provided with a transparent front. This apparatus is mounted on a camera tripod, and is observed by throwing a black cloth over the head. The air to be tested for inflammable gas is pumped over the flame by dropping the end of a flexible tube into the culvert, and compressing a rubber ball provided with suitable valves. A constant stream of the air is thus caused to pass over the hydrogen flame, and by the appearance and dimensions of the flame-cap produced, gas is detected and its percentage is accurately measured. The hydrogen flame can be adjusted to two standard heights, and thus percentages of gas from 0·2 to 5 can be detected and measured.

Geometric wall brackets were exhibited by the Rev. F. J. Smith, F.R.S., and Prof. C. V. Boys, F.R.S. The brackets have been designed with the object of providing wall supports with definite position for physical apparatus. After the apparatus and bracket have been adjusted, they may be removed, and at any time immediately restored to their original position. This is found to be convenient where a class or lecture room is used for some portion of a day only for physical demonstration. The construction is as follows:—Three small projections, A, B, C, are fixed to the wall, one of the two upper projections is furnished with a three-sided indentation, the other with a V-groove, the third is a flat surface; two hemispherically ended screws drop into the upper projections, and the third screw at the bottom of the bracket rests against the flat surface.

Geometric steady blocks were also exhibited. These have been designed so as to rest each on the one below it, upon six independent small surfaces, so as to be geometrically clamped. Thus any number of blocks may be piled to the desired height, and carry physical apparatus with perfect steadiness. Both square and triangular forms were shown.

M. Maurice d'Ocagne, Professor at the École des Ponts et Chaussées, exhibited a very complete series of "abaques" of his invention, intended to perform certain calculations, such as the solution of a cubic equation, or of Kepler's equation, and generally of any equation involving three or four variables. The interest was purely mathematical, appealing to a select few; but the applications of the principle are numerous and important.

Mr. W. Barlow exhibited models to show the nature of the repetition in space which characterises a homogeneous structure having cubic symmetry.

Specimens of ancient "astrolabes" and other instruments were exhibited by Mr. Lewis Evans.

Messrs. Read, Campbell, and Co. showed "aerators" for aerating water and other liquids. The aerator is used in combination with a soda-water bottle and patent stopper. It is made of sheet steel, and contains compressed carbonic acid gas; the soda-water bottle being filled with water or other liquid, the aerator is inserted in the stopper, and the closing of the latter liberates the gas, producing strongly aerated water or other liquid. The aerators may be charged with other gases and used for other purposes than aerating liquids.

There were exhibited by the Meteorological Council: (1) Current charts of the Indian Ocean for the months of January, April, July, and October. The currents shown on these charts had been generalised from a very large number of observations, the arrows and figures attached to them indicating the direction and maximum and minimum velocities of the current likely to be experienced at any particular spot. (2) Wind charts of the South Indian Ocean, between the Cape of Good Hope and New Zealand, for the months of January, April, July, and October.

These charts showed, by a new form of wind rose, recently adopted by the Meteorological Council, not only the frequency of the winds, but their strength, over areas contained by 3° of latitude and 10° of longitude. Isobars were also drawn on the charts so that the relation of the winds to the barometrical pressure could be compared. In the corners of the wind areas the percentage of fog and the number of weather observations were given. A small inset chart showed the temperature of the air, which was represented by isothermal lines, and the limits of fog were also indicated. (3) Sea surface temperature charts of the South Indian Ocean, between the Cape of Good Hope and New Zealand, for each month of the year.

Coming now to natural science, Dr. Woodward, F.R.S., showed a part of the collections made by Dr. C. I. Forsyth Major in Madagascar, 1894–95; and Dr. J. W. Gregory exhibited a geological map of part of British East Africa, with sketches, sections and specimens. The map showed the main features in the structure of British East Africa. The region consists of a plateau of Archean rocks (gneiss and schist) sinking beneath strips of Carboniferous and Jurassic deposits in the coastlands, and buried by piles and sheets of volcanic rocks in the interior. Volcanic activity probably lasted from the Cretaceous to the present day. The lavas have been ejected by plateau eruptions and by crater eruptions. The former poured forth sheets first of trachytoid phonolite, and then of basalt. The country is traversed by the Rift Valley, on the floor of which are thick series of lacustrine deposits; on its walls are the terraces of extinct lakes. Dr. Gregory also showed specimens of Hemiptera (*Flata nigricincta*, Walk.), the colonies of which resemble inflorescences. Mr. H. W. Seton Karr, and Sir John Evans, K.C.B., Treas.R.S., exhibited (1) palæolithic implements from Somaliland; (2) palæolithic implements from Somaliland, ogether with European, Asiatic, and African specimens for comparison.

Gold nuggets showing internal crystalline structure, formed an exhibit by Prof. Liversidge, F.R.S. The specimens (Australian) had been sliced and polished, and then etched with chlorine water or other reagents, so as to show the internal crystalline structure and the presence of enclosures of quartz, iron oxide, &c.

Prof. McKenny Hughes, F.R.S., exhibited (1) specimens illustrating the amount and mode of shrinkage of bog oak; (2) mulberry, showing symmetry in the twigs and asymmetry in the leaves; (3) travertine lining a wooden pipe, and reproducing all the details of the surface on which it was thrown down.

Photographs of "cup and ring" markings naturally formed upon stucco, were exhibited by Mr. C. Carus-Wilson. The wall of a house, built about forty years ago, was covered with stucco. Alternations of temperature, to which the face of the wall had been subjected, had rearranged the particles composing the stucco, producing linear and annular ridges and depressions similar to those occasionally seen on rock-faces, and usually ascribed to the hand of prehistoric man.

Prof. Ray Lankester, F.R.S., showed a cast of enlarged model (eight times natural size) of the type specimen of *Amphitherium prevostii* (lower jaw, Stonesfield slate). Casts taken direct from these very small jaws are of little use. Drawings necessarily fail to show clearly the modelling of the teeth. Accordingly Prof. Lankester has obtained, through the skill of Mr. Pycraft (one of his assistants in the Department of Comparative Anatomy, Oxford), a careful wax model of each of the unique Oxford mammalian fossil jaws, eight times the natural size. A coloured cast of the wax model of one of these jaws, the type specimen of Amphitherium, was exhibited, and similar casts will be offered to the chief European and American museums.

The Marine Biological Association had on view a series of specimens illustrating the boring habits of certain marine animals, amongst them being a series of shells showing the gradual disintegration due to the action of boring sponges. Some rare or interesting marine organisms recently found at Plymouth were also shown by the Association.

Mr. Walter Garstang demonstrated certain adaptations, subservient to respiration, in sand-burrowing Annelids and Crustacea. In aquatic animals which burrow in fine sand, the activity of the gills would be impaired by the accumulation of sand around the gills, or in the course of the respiratory currents. To prevent this, the water before passing to the gills is sieved in the Annelid *Aphrodite* by a felted mass of fine hairs, and in Decapod Crustacea by the hairs bordering the branchiostegite. In the crabs *Atelecyclus* and *Corystes* the normal respiratory current is reversed, and the water passes to the gills through a sieve-tube formed by the interlocking of rows of special hairs on the apposed antennæ. In *Atelecyclus*, which burrows to a shallow depth, the reversal of the current takes place only when the crab is imbedded; in *Corystes*, which burrows deeply, the antennal tube is elongated, and the reversal of the current is all but constant.

A wax model of a single electrical nerve cell from the spinal cord of *Malapterurus electricus* (River Senegal), and microscopic serial sections, was exhibited by Dr. Gustave Mann. The model was made from camera lucida drawings of a complete series of sections through the cell. It showed one axis cylinder process, and an enormous number of dendritic processes which in many cases are joined by their ends to form loops. The model was 500 times the natural size of the nerve cell.

A selection of the dried plants collected in Tibet by Mr. St. George R. Littledale, was exhibited by the Director, Royal Gardens, Kew. The plants were collected in the Gooring Valley, between Tengri Noor and Lhassa, in lat. 30° 12′ N., and long. 90° 25′ E., at an altitude of about 16,500 feet; they represented the general character of the vegetation.

Nuclear division in the spores of *Fegatella conica* was shown by Prof. J. B. Farmer. The spindle in these spores is of a very unusual form at first, but becomes normal subsequently. The primary cell wall remains free in the cytoplasm, and during the two second divisions of the nuclei it becomes rotated through an angle of 90°, and the spore is thus divided into four cells. The ultimate position taken up by the walls corresponds with that of a system of soap films, introduced into a box similar in shape to that of the Fegatella spore, when the cavity of the box is to become divided into four chambers by such films.

Mr. A. Francis Dixon showed a model to illustrate the method of reconstruction from serial microscopical sections by the use of glass plates. This exhibit illustrated a method of reconstruction which is especially useful in tracing the crossing and branching of fine structures, such as nerves and vessels in the embryo. The model was composed of a number of glass plates covered with a transparent varnish. On each plate was traced the outline of a portion of a section belonging to a series, multiplied in the case shown fifty diameters. The thickness of each glass plate was fifty times that of the section drawn on it. When the different plates were placed one over the other in order, a transparent model of the whole structure results, multiplied fifty times. The model shown illustrated parts of the distribution of the trifacial nerve in a rat embryo of the fifteenth day.

During the evening two lectures, with demonstrations by means of the electric lantern, took place. At one of these Prof. Meldola described the exhibits, by M. le Prof. Lippmann, of colour photographs by the interferential method. The photographs, which were projected upon a screen, represented stained glass windows, landscapes and flowers taken from nature, vases, and a portrait from life.

Experiments with liquid air were described by Prof. Dewar, F.R.S., at the second of the two demonstrations.

THE IRON AND STEEL INSTITUTE.

THE annual general meeting of the Iron and Steel Institute was held last week in London, commencing on Thursday, the 7th inst., and continuing over the following day. From the Report of the Council it would appear that the Institute is in a flourishing state. The membership is increasing, and naturally with it the income, whilst the expenditure shows a very remarkable diminution during the last two years. Those who are acquainted with this society know that this lessening cost of management has not been accompanied by any diminution of efficiency.

On the members assembling on Thursday morning, Sir Lowthian Bell occupied the chair in the absence of the President, Sir David Dale, who was prevented from being present by indisposition. The first business of the meeting was the presentation of the Bessemer medal, which had been awarded to Dr. Hermann Wedding, Professor at the Berlin School of Mines, in recognition of the services he has rendered to the iron and steel industries by his valuable contributions to metallurgical literature. An interesting feature in this ceremony was the presence of Sir Henry Bessemer, the venerable founder of the modern steel industry, who made a speech congratulating Dr. Wedding on being selected by the Council as the recipient of the medal.

The following list of papers to be read and discussed was on the agenda.

"On the Rate of Diffusion of Carbon in Iron," by Prof. W. C. Roberts-Austen, C.B., F.R.S.

"On some Alloys with Iron Carbides," by J. S. de Benneville, of Philadelphia.

"On Mond Gas as applied to Steel Making," by John H. Darby, of Brymbo, North Wales.

"On Hot Blast Stoves," by B. J. Hall, of Westminster.

"On the Hardening of Steel," by H. M. Howe, of Boston, U.S.

"On the Introduction of Standard Methods of Analysis," by Baron Hans Jüptner von Jonstorff, of Neuberg, Austria.

"On the Production of Metallic Bars of any Section by Extrusion," by Perry F. Nursey, London.

"On Mr. Howe's Researches on the Hardening of Steel," by F. Osmond, of Paris.

"On the Treatment of Magnetic Iron Sand," by E. Metcalf Smith, of New Zealand.

"On the Making of the Middle Lias Ironstone of the Midlands," by E. A. Walford, Banbury.

Mr. Hall's paper was first taken. It described a form of hot blast stove which has now been in use many years, the first, we believe, having been erected about twelve years ago. It is known as the Ford and Moncure stove, and is of fire-brick, having the ordinary chequer work, although the arrangement varies somewhat from the Cowper or Whitwell patterns, the chief difference being that the stove is divided by walls into four parts. The object is to give facilities for clearing from dust. When the change is made from gas to air the whole of the blast is passed through one of the four divisions, naturally in a very concentrated form. This blows the dust out of the chimney-top, or deposits it in the flues, from whence it can be removed at convenient times. Details given by the author showed that the stoves have a long life, a fact which is perhaps as much due to the excellent proportion on which they are designed as to any special novelty in the construction. From what was said during the discussion, it would appear that the dust-removing device answers satisfactorily.

The next paper taken was Mr. Nursey's contribution, which described a very interesting departure in the production of metal bars of various sections.

The author stated that the system of manufacture was the invention of Mr. Alexander Dick, the inventor of Delta metal. It related to the production of all kinds of metallic sections, from thin wire or plain bars to complex designs, by simply forcing metal, heated to plasticity, through a die by hydraulic pressure. He referred to the fact that although the principle of extrusion was employed in the manufacture of lead pipe and lead wire, yet the temperature was very much lower than in Mr. Dick's system, which required the metal to be red-hot, or about 1000° F. The process consisted in placing the red-hot metal in a cylindrical pressure chamber, or container, at one end of which is a die. Upon pressure being applied at the opposite end the plastic metal is forced through the die, issuing therefrom in the form of rods or bars of the required section and length. The container of the first apparatus made was a solid steel cylinder, bored out to the required diameter to form the chamber for the hot metal, and heated in a coke fire. In practice, however, it was found that the strain set up by the unequal expansion and contraction of the walls of the cylinder, added to that caused by the internal pressure applied to force the metal through the die, developed cracks in the cylinder which rendered it useless. After a long series of experiments with various kinds of steel cylinders, Mr. Dick abandoned the solid wall principle and devised a built-up container. It is composed of a series of steel tubes of different diameters, placed one outside the other, with annular spaces between them, these spaces being filled with a dense non-conducting packing. This device proved perfectly successful, and machines on this principle are now in operation on a commercial scale at the works of the Delta Metal Co., in Germany, and at one of the large Midland metal rolling mills. These machines are served by two men and one boy, so that the cost of labour per ton is very small. The author described the working of the system, and referred to the great variety of sections, some of a very complex nature, produced in Delta metal, brass, aluminium, aluminium bronze, and other alloys and metals, samples of which were exhibited on the table of the theatre. They ranged from wire weighing about 1/100 of a pound per foot run, to heavy rounds, squares, and hexagons weighing 40 lb. and over per foot run. Among the examples was a complex moulding that could not possibly have been made by rolling in the usual way followed for making metal articles of this nature. Mr. Nursey pointed out that the pressure put upon the metal greatly increased its strength, and at the same time rendered it still more homogeneous. Some tests made at Woolwich Arsenal with Delta metal bars produced by extrusion showed a tensile strength of 48 tons per square inch with 32·5 per cent. elongation on 2 inches, as against 38 tons per square inch tensile strength and 20 per cent. elongation of rolled bars of the same metal. The author concluded by stating that Mr. Dick was engaged on experiments with the view of producing sections in iron and steel similar to those at present turned out in Delta metal.

In the discussion which followed the reading of Mr Nursey's paper, Mr. Snelus described a process of covering telephone cable with lead, somewhat analogous to that referred to by the author. This cable contained over 150 wires, and was three inches in diameter. The fluid lead was pressed over it through dies. The great difficulty in all processes of formation by extrusion is to get a material for making the dies which will stand the hard usage to which they are put. Mr. Dick uses tungsten steel, a very hard material which does not require tempering; this, it seems, is good enough for Delta metal, one of the many new bronzes, and for the other materials mentioned. But if it were necessary to deal with metals having a higher melting point, a still more refractory metal would be required, and one of equal hardness, as the dies must not only withstand heat, but erosion. Mr. Snelus was of opinion that if the container, or cylinder, used for forcing out the fluid metal, were made of some highly refractory earth, that steel pipes could be made in this way. That, of course, would be a great commercial success, for not only could the pipes be cheaply manufactured in long lengths, but the quality would doubtless be much improved. In the present day of water-tube boilers this is a matter well worth considering. The difficulty in making steel tubes, however, does not appear to rest with the production of a refractory container. Mr. Dick said that he had made steel bars by extrusion, although it was done accidentally, and the trouble was, not that the cylinder gave way, but that the dies would not stand the work; if, therefore, an ingenious metallurgist can discover an alloy as hard as tungsten steel, and more refractory, he will possibly make a considerable fortune.

Mr. Metcalf Smith's paper was next taken. The author described the method adopted in New Zealand of smelting, or perhaps one should say melting, the iron sand found so largely in that country. The paper stated that the sea cliffs on this part of the coast consist of a combination of silica sand and a rich magnetic iron sand; the gradual crumbling of these cliffs, together with large quantities of iron sand brought down by the rivers and streams, draining the slopes of Mount Egmont, result in a deposit of almost pure iron sand on the beach, a large proportion of the lighter silica sand being washed out to sea. Excavations have been made on the beach showing a depth of iron sand of fourteen feet, whilst the same material has been dredged up at a distance of three miles out to sea. Nature seems to have devised this district most fitly for an iron industry; for not only are these vast deposits of magnetic iron so easily obtainable, but in close proximity there are extensive coal beds. There is also limestone containing 88 per cent. of calcium carbonate, timber for charcoal if required, and, indeed, provision for supplying all the needs of iron manufacture. Here is an analysis of the iron sand, made by Sir James Hector:

Peroxide of iron } Protoxide of iron }	82·0
Oxide of titanium	8·0
Silica	8·0
Water and loss	2·0
	100·0

Of course iron sand is known in other countries besides New Zealand, and efforts have often been made to smelt it. The difficulty, however, has been that it comes down and chokes the furnace when melting begins, so that it descends to the hearth unreduced. This is got over in New Zealand by kneading it into bricks with clay, which is found close by. In this way hard and compact lumps are procured, which will stand the pressure and grinding action in travelling through the furnace. One ton 12 cwt. of iron sand is mixed with 10 cwt. of clay; and in this

way, what is equivalent to a very rich ore is produced. The pig iron made gives an excellent analysis. It is not, however, necessary to smelt all the iron sand in this way, for a certain part of it can be mixed with fluid iron, tar being added. The liquid metal will melt and absorb the iron sand, the tar giving sufficient carbon to retain the metallic iron in a fluid state. There is, of course, a saving in cost in this method of procedure, and the metal may be run direct for castings, thus avoiding the loss in remelting. Bar iron is made by puddling from tarred iron sand and smelted metal. In the Siemens furnace, also, the same method of procedure is followed. Figures are given in the paper as to the cost of these processes, but the most remarkable details are those referring to the quality of the product. Thus we are told that by the treatment described, bar iron, equal in quality to BBH, can be produced for £7 per ton, and wrought iron, which will give what the author truly described as "the extraordinary tensile stress of 52 tons to the square inch." One would be inclined to describe this tenacity in wrought iron, not only as extraordinary, but as almost incredible; at any rate, one would wish to see the test authenticated by at least more than one experimenter of high reputation before accepting it as unquestionable. This would be more especially the case if, as we understood the author to say, the elongation was $33\frac{1}{2}$ per cent.

Mr. Walford's paper was next taken. Its object was to describe the character of the Middle Lias ironstone of the Midlands and its organic origin, and the making of the stone and its ferruginous changes.

At the conclusion of the reading of this paper the meeting adjourned until the next day.

On the members again assembling on Friday morning the paper of Baron Jüptner was the first taken, being read by Mr. H. Bennett Brough in the absence of the author. This was a very long contribution consisting of thirty-six pages, but, as was said during the discussion which followed its reading, it was not a word too long. The subject is one of great importance, and has been far too long neglected. The want of uniformity in analysis has led to much confusion and consequent loss of money in the iron and steel industries. In a general description of the meeting, such as this, it would be impossible to do justice to a subject of this magnitude, and at present we can only make brief reference to the proposals contained in the paper, hoping to return to the question so as to deal with it at greater length on a future occasion. A large part of the paper was occupied in giving examples of discrepancies in analyses; thus, in an instance quoted, a chill roll was examined in two laboratories, and quite incredible differences were obtained. In one case the carbon was returned as 3·5 per cent., in another 2·785 per cent. Silicon in the first analysis was given at 1·3 per cent., the second laboratory gave 0·668 per cent. Other instances almost as striking were quoted by the author. What is proposed now to be done is to establish an international laboratory in Switzerland. All the important nations are to nominate honorary directors of work. For the purposes of making analyses, however, paid investigators will be necessary. Dr. Wedding, who spoke during the discussion, said that it was estimated the cost would be about £3000 a year, and he thought that if 300 of the principal iron and steel works in the world would contribute yearly £10 apiece, the work for a period of ten years could be done. Sir Lowthian Bell was of opinion that there should be no difficulty in getting this amount of money, and promised that his own works should contribute. It is perhaps unnecessary to point out that English iron and steel works are in some cases—there are, of course, notable exceptions—lamentably deficient in the scientific department. Mr. Stead, whose experience is very wide, and who speaks as a disinterested observer, said that in some establishments of considerable importance the chemist only received a salary of £100 a year. How can a man be expected, not only to work with that enthusiasm with which all scientific men must work for their labours to be effective, but to keep abreast of knowledge by the purchase of books, and subscriptions to technical or scientific societies, on such a stipend as this, which can allow no surplus after the barest necessities of life have been supplied? Mr. Stead pointed out that technical libraries were not common enough in this country, and he would suggest that in all large manufacturing centres libraries of that nature should be instituted. This, however, would not quite meet the difficulty. Abroad, especially in Germany, one finds iron and steel works have libraries of their own, the collection of books they possess being sufficiently large in most cases to be dignified by the name. Unfortunately in England, beyond a few elementary treatises or text-books, very little literature is seen in the laboratories, the chemist too often contenting himself with following well-known and stereotyped methods of analysis, and not troubling himself with any original work which might lead to fresh industrial developments. A good deal has been heard lately about German competition in the iron and steel trade, and there has been an inclination to attribute it to higher wages paid in this country. It may be, however, that there is something to be said not only against labour, but against capital in this matter; and certainly German steel makers have gone ahead of those in England in many cases. We have in mind, perhaps just now more especially, the development of the basic steel industry, the invention of which originated in this country. By the exercise of greater foresight, greater enterprise, and improvement in processes, Germany has gained a commercial advantage from which England is now suffering. In the discussion that followed the reading of the paper, one or two suggestions were made which should be put on record. Prof. Arnold drew attention to the effect of segregation, of which he has met with some striking examples of late. In a tyre examined, sulphur was in one case 1 per cent.; in another sample, taken an inch and a half from the first, the sulphur was ·043. Mr. R. A. Hadfield said that allowance should be made for previous treatment of metal, and, in considering the history of a sample, its size, previous mechanical treatment, and from what part of the ingot it was taken, should be noted. Dr. Readel was of opinion that the iron and steel industry was behind other industries in devising standard methods of analyses. The British Association Commission, he said, did good work, but there was the defect of want of organisation. Each member went on his own line, so that the same ground was covered more than once. An orderly scheme of procedure was the first thing necessary, certain work being allotted to different individuals; he had had, recently, occasion to look into the subject of chromium, and had found even for this metal some thirty or forty processes for determining its presence. What was necessary was that some one with authority should make a selection showing that which might be the most desirable to retain. Mr. Ainsworth made a suggestion which it is to be hoped will not be lost sight of. The accumulated funds of the Institute are about eight or nine thousand pounds, and with the improved management of the present day, the sum is likely to be increased at a rapid rate. Mr. Ainsworth pointed out that it is not desirable to hoard this money, and no better means could be devised for spending it than bringing out of the present chaos an orderly method of chemical analysis. The suggestion was warmly supported by the Chairman, Sir Lowthian Bell.

It may be said that chemical analysis has fallen somewhat into disfavour with iron and steel makers of late, and also with engineers, the tendency being to trust wholly to physical experiment, aided latterly by microscopical examination. It is certain, however, that nothing can take the place of chemistry in metallurgical research; and the disfavour with which it is now regarded is not the result of faults inherent to the system of chemical examination, but to the imperfect manner in which it is carried out.

Mr. Darby's paper was taken next. It described a process which promises to be of great importance in the iron and steel trade, by means of which sulphate of ammonia is obtained from producer gas without the gas being rendered unfit for steel making. For many years steel makers have had such a process in view, and experiments have been made with a view to bring it to practical shape. So far as we are aware, however, they have all hitherto resulted in failure, or, at any rate, have not been a commercial success. Mr. Darby's experiments, however, go to show that Dr. Mond has solved the problem. We have not space to enter into details here, but must refer our readers to the very interesting paper which will be published in the *Transactions*, and in which the method of working the apparatus is shown by a diagram. Although the experiments of Mr. Darby were carried out on a practical scale, the furnace was a small one; but this was rather against the process, as it is more difficult to work a small steel furnace, and keep the metal fluid, than a large one. The plant required for carrying out the process is undoubtedly very costly, but as the return in ammonia will enable a dividend of 25 per cent. to be paid on the outlay, there doubtless will be little difficulty in finding the money in large steel works. It is to be hoped that the English steel makers will not neglect to inquire into and consider this oppor-

tunity of adding to their returns, and will not once more allow the foreigner to develop a system originally devised in this country.

In the discussion on the paper, several steel makers, who had seen Mr. Darby's plant in operation, spoke as to the excellent way in which the furnace worked when using gas which had been treated for the extraction of the ammonia.

Prof. Roberts-Austen next gave a brief address on the diffusion of carbon in iron, he not having prepared a paper in the usual way. The subject has recently been described by the same author in the Bakerian Lecture of the Royal Society and will shortly be treated in these columns; it is therefore unnecessary for us to go into the matter on the present occasion.

The remainder of the sitting was almost wholly occupied by the reading and discussion of M. Osmond's and Mr. Howe's papers, the paper of M. de Benneville being taken as read. It would be impossible at the end of a report of this nature to deal with the highly controversial matters which form the subject of these two papers; and indeed, without the introduction of the micro-sections supplied by Mr. Howe, the matter would not be intelligible. The allotropic theory of the hardening of steel, which has already caused so much discussion, did not appear to be carried very much further on Thursday last, or, at any rate, the majority of those present at the meeting did not seem to see their way much further towards the end of the problem. M. Osmond welcomes Mr. Howe as a friend and ally. He looks on the latter's carbo-allotropic theory as not antagonistic to his own. The discussion was confined principally to Prof. Arnold and Mr. Hadfield, who are the chief opponents of the school represented principally by M. Osmond and Prof. Roberts-Austen, now, we suppose, with Mr. Howe as an ally.

The summer meeting of the Institute is this year of an unusually ambitious nature, and will be held in September in Bilbao, a steamer having been chartered for the conveyance of members to that port. The vessel is the Orient liner *Ormuz*, which will also serve as a floating hotel for members during the meeting.

A REMARKABLE DUST-STORM.

THE American journal *Electricity* for February 19 contains an account of an unusual kind of storm which occurred in January of this year. The details were communicated by L. H. Korty, telegraph superintendent of the Union Pacific System, of Omaha, Neb. It was on the telegraph lines of this system between Weber and Peterson, Utah, that considerable difficulty was experienced in working, owing, as it is stated, to the peculiar character of the storm in question. The description is as follows:—

"On the afternoon of January 16, a very peculiar rain-storm occurred in Eastern Utah and Western Wyoming, along the Union Pacific Railway, extending from Ogden, Utah, to Evanston, Wyoming, a distance of 75 miles. The rain consisted of salt water or brine. The clothing of persons exposed to the shower had, when dry, the appearance of having been sprinkled with whitewash. The windows in the stores and residences at Evanston were so encrusted with salt deposit as to make it impossible to look out. Dr. C. T. Gamble, of Almy, Wyo., a gentleman of undoubted trustworthiness, states that the storm deposited in Almy alone 27 tons of salt. 'This assertion may appear fabulous,' says the doctor, 'but nevertheless is true, as it has been proved by carefully estimating the quantity on a given surface in different parts of the camp. The area of Almy is something over nine miles, and three tons to the mile would make 27 tons of the sodium deposited. The salt if collected and sacked would make ten ordinary wagon-loads. Those who doubt the above statements, go to figuring.'

"The salt-storm lasted about two hours. After it had ceased raining, the sun came out, and as fast as things dried they turned a whitish colour, and it was found that everything was covered with a thick coating of salt. Cars, buildings, trees, telegraph poles, insulators and wires all looked ghastly in their white coats. Through Weber Cañon the salt storm turned into snow later. A peculiar effect of the salt deposit on the telegraph poles, arms and insulators through Weber Cañon was noticed in operating the wires. During the day, when the sun came out, the wires worked clear and without interruption, while at night, when it turned cold, the wires were rendered unserviceable, which was attributed to the fact that the snow, having melted, some during the daytime and again freezing at night, created a moisture in conjunction with the salt deposit underneath, so as to entirely destroy the insulation of the wires. After several unsuccessful attempts to remove the cause of the trouble, an engine with a pump and long hose was sent over the line, and the deposit thoroughly washed off the poles and fixtures for a distance of 40 miles. The wires of the Rio Grande Western Railroad between Ogden and Salt Lake City were slightly affected in the same way, as were also those of the Southern Pacific for a short distance west of Ogden."

It has been suggested, as an explanation of the facts, that the salt was raised in vapour over Great Salt Lake, and was carried by the wind and deposited over the country for many miles to the eastward. This, of course, could not have happened, as *salt could not be raised in vapour*. It seems likely, however, that the white residue may have had the appearance of salt, but was not actually salt. Would not a more reasonable explanation be that fine white dust in the region about the lake may have been carried into the upper regions by the wind, and after traversing some miles brought to earth again owing to the condensation of the vapour surrounding them?

SCIENCE IN THE MAGAZINES.

THIS month's magazines contain numerous articles on scientific topics or with scientific bearings. Röntgen photography naturally forms the theme of several contributions. The *Quarterly Review* contains a short descriptive account of methods employed, results obtained, and theories propounded, and even blossoms into illustrations reproduced from radiographs taken by Mr. A. A. C. Swinton. The *Century Magazine* has "a Symposium on the Röntgen Rays," the writers being T. C. Martin, R. W. Wood, Elihu Thomson, Sylvanus P. Thompson, J. C. McLennan, W. J. Morton, and Thomas A. Edison. The result of this composite article is vain repetition of experimental conditions, and a confusion of tongues; Prof. Thompson referring to pictures obtained by Röntgen rays as "sciographs," while other writers describe them as "shadowgraphs," and all the illustrations are designated "cathodgraphs."

Dr. St. George Mivart writes on "Life from the Lost Atlantis" in the *Fortnightly*, his paper being concerned chiefly in pointing out the significance of the discovery of *Cænolestes obscurus*, a still-existing survivor of Ameghino's Epanorthidæ, and the representative of a new family of recent marsupials, described by Mr. Oldfield Thomas before the Zoological Society on December 17, 1895.

"This little, apparently insignificant, mouse-like creature," to quote the author, "turns out to be an animal of extreme interest, for it affords strong evidence that what we now know as South America and Australia must have been connected, and the Atlantic at least bridged by dry land, if even an Antarctic continent may not have existed, of which South America and Australia are divergent and diverse outgrowths."

Mr. G. E. Boxall puts forward, in the *Contemporary*, the view that the vast sedimentary plains of Australia, which thirty years ago were so "rotten" that no stock could be kept upon them, have been trampled into compactness by large herds of cattle and sheep. He gives reasons for believing the dry plains of Western Australia to be similar to those described by Oxley and others as once existing in the delta of the Murray, where about one hundred millions of sheep are now pastured, besides large herds of cattle and horses; and therefore he thinks that the present sandy plains will sooner or later be consolidated and rendered secure for stock. He concludes:

"The plains of Australia are, from the accounts given of them by explorers in all parts of the continent, singularly alike, and if the plains of Northern and Western Australia can be consolidated by the trampling of stock, as I believe those of the eastern districts have been, the time is not far distant when the word 'desert' may be wiped off the map of Australia, and the true character of its vast plains become more generally understood and appreciated."

Psychologists will be interested in a paper by Mr. Havelock Ellis, in the same review, on "The Colour-Sense in Literature." Mr. Ellis has examined the works of a series of imaginative writers, usually poets, dating from the dawn of literature to the present time, and has noted the main colour-words that occur, and has also noted how these words are used. His paper

contains the numerical results arrived at, together with certain observations suggested by them. The tables given lend support to the following interpretation :—

"The predominance of green or blue—the colours of vegetation, the sky, and the sea—means that the poet is predominantly a poet of nature. If red and its synonyms are supreme, we may assume an absorbing interest in man and woman, for they are the colours of blood and of love, the two main pivots of human affairs, at all events in poetry. And where there is a predominance of black, white, and, I think I would add, yellow—the colours that are rare in the world, and the colour of golden impossibilities—there we shall find that the poet is singing with, as it were, closed eyes, intent on his own inner vision. . . . Although I cannot claim to have put this numerical test of colour-vision into a final shape, there can be little doubt that it possesses at least two uses in the precise study of literature. It is, first, an instrument for investigating a writer's personal psychology, by defining the nature of his æsthetic colour-vision. When we have ascertained a writer's colour-formula and his colours of predilection, we can tell at a glance, simply and reliably, something about his view of the world which pages of description could only tell us with uncertainty. In the second place, it enables us to take a definite step in the attainment of a scientific æsthetic, by furnishing a means of comparative study. By its help we can trace the colours of the world as mirrored in literature from age to age, from country to country, and in finer shades among the writers of a single group."

Another article in the *Contemporary* is of scientific interest : it is on "The Proposed Gigantic Model of the Earth," by Dr. A. R. Wallace. It may be remembered by our readers that M. Elisée Reclus has drawn up a scheme for constructing a terrestrial globe on a scale of one-hundred-thousandth the actual size, that is, 418 feet in diameter. Another globe would be required as a cover for the actual earth-model, so that the expense of such a duplex structure would be enormous. Dr. Wallace gives a qualified support to M. Reclus' proposal ; for he thinks only one globe should be constructed, showing all the great geographical features of the earth on its outer surface, while on the inner surface would be formed that strictly accurate model which M. Reclus considers would justify the expense of such a great work.

Miss Mary Kingsley contributes to the *National* an interesting account of her ascent of "The Throne of Thunder," or the Peak of Cameroons, the highest point on the western side of the African continent. Twenty-seven white men have reached the peak, and Miss Kingsley describes the twenty-eighth ascent, the second successful one from the south-east face. In the same review Mr. A. G. Boscawen, M.P., gives his impressions of Japan, and concludes his remarks with a few words about British commercial interests in the Far East. It is satisfactory to note his remarks on the advantages to be gained by the appointment of commercial and technical advisers to foreign Legations. He says :—

"And now I would suggest what I have suggested elsewhere, that the Government ought to give a helping hand by appointing a commercial *attaché* to the Legation at Tōkyō, who I feel sure would prove most useful at the present moment, when the Japanese are friendly to us, and are certainly inclined to buy from us if we will only take the trouble to adapt our manufactures to their markets. Such an official, by keeping us constantly informed at home of what articles the Japanese require, would prevent a large portion of our trade from going to foreigners, especially to the Germans and Americans, who have for years taken far more trouble than we have to secure the goodwill of the Japanese."

A passing mention must suffice for the remaining articles of scientific interest in the magazines and reviews received. Sir Robert Ball writes on "The Scenery of the Moon," in the *Strand Magazine*, his description being illustrated by reproductions from lunar photographs. Miss Agnes Giberne treats the well-worn theme of "The Far Distance of our Universe," in *Chambers's Journal*, which also contains popular articles on the electric supply of London, jumping beans, and house-flies. Some suggestive points in connection with the evolution of language will be found in the article entitled "The Genesis of Expression," by M. L. Johnson, in the *Westminster Review*. A well-illustrated paper on "The Evolution of the Trotting Horse," contributed by Mr. Hamilton Bushey to *Scribner*, is not without interest to scientific readers. Under the title "Through Scientific Doubt to Faith," the *Quarterly Review* traces the mental history of Romanes, as evidenced by his own works, and in the lately published "Life and Letters," written and edited by his wife. The article is a complacent statement from the religious side. The Viscount Harberton writes on "Muzzling and the Prevention of Rabies" in the *Humanitarian*. Mr. P. C. Knapp brings forward evidence, in the *Century*, against the view that nervous disorders are increasing, and shows that, without more evidence in its favour, the belief in the greater nervousness of Americans is an error. Finally, the *Geographical Journal* contains Mr. St. George Littledale's account of "A Journey across Tibet, from North to South, and West to Ladak," and Mr. Edward A. FitzGerald's paper on "The First Crossing of the Southern Alps of New Zealand" Attention may profitably be drawn to the maps which illustrate Mr. Littledale's journey, and to a new map of the Upper Kuyuni River, British Guiana, from a recent survey.

THE METRIC SYSTEM IN THE UNITED STATES.

STRENUOUS efforts are being made by the American Metrological Society to secure the adoption of the Bill making the use of the metric system obligatory in the United States after a specified date. Letters have been sent to all who are interested in the question, soliciting their help and influence, and petitions are being numerously signed and sent in to Representatives. The Committee on Coinage, Weights and Measures, of the House, recently reported unanimously in favour of the Bill, and the introduction and conclusion of their interesting report are reprinted in *Science*, from which source the subjoined summary has been made.

For more than a generation after the construction of the constitution, the American people lived with no legal standard by which could be determined even the amount of metal which went into the coin that came from their mints. Gallatin procured from France a platinum kilogram and meter in 1821, and from England a troy pound in 1827, and in 1828 the latter was recognised as the standard for mint purposes by the following Act :

"For the purpose of securing due conformity in weight of the coins of the United States to the provisions of this title, the brass troy pound weight procured by the Minister of the United States at London in the year eighteen hundred and twenty-seven for the use of the mint and now in custody of the mint at Philadelphia, shall be the standard troy pound of the mint of the United States, conformably to which the coinage thereof shall be regulated."

Meantime both the people and the Government were using such weights and measures as were nearest at hand, derived in the main from the English ancestry, but made by themselves without any authoritative standard for comparison, and as a consequence differing materially from each other. In 1830 the Senate directed the Secretary of the Treasury to have a comparison made of the standards of weight and measure used at the principal custom houses of the United States, and report the same to the Senate. This was done, and large discrepancies and errors were found to exist. These discrepancies were nullifying and violating the provision of the Constitution which prescribes that "all duties, imposts and excises shall be uniform throughout the United States." Varying scales and varying measures inevitably produced varying rates of duty. The Treasury Department, therefore, in the exercise of its executive power and as a necessary incident and means to the execution of the law and the observance of the Constitution, adopted for the use of that Department the Troughton scale, then in the possession and use of the Coast Survey, as the unit of length, and the troy pound of the mint as the unit of weight. From the latter the avoirdupois pound was to be derived, assuming that there were 7000 grains in the pound avoirdupois to 5760 in the pound troy. For measures of capacity the wine gallon of 231 cubic inches, and the Winchester bushel of 2150·42 cubic inches, were adopted. This gave to the Treasury Department the basis of a system of weights and measures to be used in its operations, and in order to promote the general adoption and use of the same throughout the country, Congress, in June 1836, adopted the following joint resolution :

"That the Secretary of the Treasury be, and he hereby is,

directed to cause a complete set of all the weights and measures adopted as standards, and now either made or in the progress of manufacture for the use of the several custom houses, and for other purposes, to be delivered to the Governor of each State in the Union, or such persons as he may appoint, for the use of the States, respectively, to the end that a uniform standard of weights and measures may be established throughout the Union."

In accordance with this resolution, sets of the weights and measures adopted for use in the custom houses were sent to the several States, and only in this indirect and inferential way have the customary weights and measures of the United States been legally recognised. By the Act of March 3, 1881, similar sets of standards were directed to be supplied to the various agricultural colleges which had received land grants from the United States at a cost not exceeding 200 dols. for each set. This law was complied with as best it could be under the limitation of cost prescribed.

Meantime the metric system had come into extensive use among other nations, and into almost universal use in the realm of exact science the world over. The Americans touched it at every turn in their commercial relations and scientific investigations. Uniformity in weights and measures throughout the world was urged not only by men of science, but by sagacious business men, seeking to keep pace with the rapidly growing tendencies to closer commercial and business relations among the nations resulting from the improved facilities of communication and transportation which had largely removed the barriers of space and distance. Hence in 1866 Congress, with the approval of the President, placed on the statute books the following law:

"AN ACT to authorise the use of the metric system of weights and measures.

"*Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled*, That from and after the passage of this Act it shall be lawful throughout the United States of America to employ the weights and measures of the metric system, and no contract or dealing, or pleading in any court, shall be deemed invalid or liable to objection because the weights or measures expressed or referred to therein are weights or measures of the metric system.

"Sec. 2. *And be it further enacted*, That the tables in the schedule hereto annexed shall be recognised in the construction of contracts, and in all leading proceedings, as establishing, in terms of the weights and measures now in use in the United States, the equivalents of the weights and measures expressed therein in terms of the metric system; and said tables may be lawfully used for computing, determining and expressing, in customary weights and measures, the weights and measures of the metric system."

To make this law of practical use the following joint resolution was adopted:

"JOINT RESOLUTION to enable the Secretary of the Treasury to furnish each State with one set of the standard weights and measures of the metric system.

"*Be it resolved by the Senate and House of Representatives of the United States of America in Congress assembled*, That the Secretary of the Treasury be, and he is hereby authorised and directed to furnish to each State, to be delivered to the Governor thereof, one set of standard weights and measures of the metric system for the use of the State respectively."

By inadvertence, and without important legal significance, the resolutions providing for furnishing the standards became a law before the Act authorising the use of the system. In the same year Congress put it in the power of the Post-Office Department to make extensive use of metric weights in its operations. The law of that year was re-stated and re-enacted in 1872, and now stands in the Revised Statutes in the following terms:

"The Postmaster-General shall furnish to the post-offices exchanging mails with foreign countries, and to such other offices as he may deem expedient, postal balances denominated in grams of the metric system, fifteen grams of which shall be the equivalent for postal purposes, of one-half ounce avoirdupois, and so on in progression."

The International Postal Convention of two years later, and which by subsequent renewals is now in force between the United States and fifty other nations, uses only metric weights and terms, and to-day the mail matter transported between America and other nations, even between the United States and England, is weighed and paid for entirely in terms of metric weights.

Here legislation on the subject of weights and measures rested till 1893. In the meantime important action was taken by the Executive Department of the Government. The progress of science, carrying with it the capability of more accurate observation and measurement, had disclosed the fact that the metric standards in use in different countries differed among themselves, and indicated that even the standards in the archives of France could be constructed with greater precision and accuracy, and preserved with greater safeguards against possible variation from influence of the elements or other forces. Hence France invited the other nations to join in an international Commission for the purpose of constructing a new metre as an international standard of length. America accepted the invitation, and was represented in the Commission, which met in 1870, and continued its labours from time to time till they were finally consummated in the conclusion of a metric convention signed on May 20, 1875, by the representatives of the following nations, viz. the United States, Germany, Austria-Hungary, Belgium, Brazil, Argentine Confederation, Denmark, Spain, France, Italy, Peru, Portugal, Russia, Sweden and Norway, Switzerland, Turkey, and Venezuela.

The first name signed to this convention is that of E. B. Washburn, the United States Minister and Representative. The treaty provided for the establishment and maintenance, at the common expense of the contracting nations, of "a scientific and permanent international bureau of weights and measures, the location of which shall be Paris," to be conducted by "a general conference for weights and measures, to be composed of the delegates of all the contracting governments." Beyond the construction and custody of the international standards and the distribution to the several countries of copies thereof, it was expressly provided as to this conference by the terms of the treaty or convention that "it shall be its duty to discuss and initiate measures necessary for the dissemination and improvement of the metrical system." This convention was duly ratified by the Senate, and since that time the United States has been regularly represented in the International Conference, and has paid its proper proportion of the cost of maintaining the International Bureau of Weights and Measures. By the terms of the convention the privilege of acceding thereto and thus becoming a party to it was reserved to any nations desiring to avail themselves thereof, and accordingly the following nations have since become parties to the convention, viz. Servia in 1879, Roumania in 1882, Great Britain in 1884, Japan in 1885, and Mexico in 1891.

New standards were prepared with extreme care and accuracy, and duplicate copies thereof distributed to the several nations. Those for the United States were received with much ceremony at the White House, January 2, 1890, by the President in the presence of members of his Cabinet and other distinguished gentlemen, and are now carefully guarded in a fire-proof room set apart for the safe-keeping of the standards of weights and measures in the Coast Survey building.

By formal order of the Secretary of the Treasury of April 5, 1893, the metre and kilogram thus received and kept were recognised as "fundamental standards" from which the customary units of the yard and pound should be thereafter derived in accordance with the law of July 28, 1866.

Meantime Congress by Act of March 3, 1893, established a standard scale for measurement of sheet and plate iron and steel, expressed in terms of both the customary and metric measures. "An Act to define and establish the units of electrical measure" was passed by the Fifty-third Congress and approved July 12, 1894. It is based on the metrical system exclusively.

From this *résumé* of United States legislation on the subject of weights and measures it appears that a legal standard of weight has been established for use in the mint, but that beyond that the weights and measures in ordinary use rest on custom only with indirect legislative recognition; that the metric weights and measures are made legal by direct legislative permission, and that standards of both systems have been equally furnished by the Government to the several States; that the customary system has been adopted by the Treasury Department for use in the custom houses, but that the same Department by formal order has adopted the metric standards as the "fundamental standards" from which the measures of the customary system shall be derived. This presents a condition of legal complication and practical confusion that ought not to continue. The constitutional power vested in Congress should be exercised.

The Committee confessed that considerable temporary inconvenience would probably accompany the change, but they

believed that this was greatly over-estimated, and that it would be of short duration. But whether the inconvenience be little or great, it must some time be encountered, and it will not be decreased by the increase of the population. It will be no easier for a hundred millions of people ten years hence to make the change than for seventy millions to-day. It is simply a question whether this generation shall accept the annoyance and inconvenience of the change largely for the benefit of the next, or shall the people of to-day selfishly consult only their own ease and impose on their children the double burden of learning and then discarding the present "brain-wasting system." The present generation must meet this test of selfishness or unselfishness, and answer to posterity for duty performed or neglected.

The Committee, after a careful consideration of the whole subject, unanimously reached the conclusion that the metric system of weights and measures should be put into exclusive use in the various Departments of the Government at such future date as shall allow adequate preparation for the change, and at the end of a fixed time thereafter that said system shall be recognised as the only legal system for general use. They, however, do not deem it wise at present to require a change in the methods of surveying the public lands, as this would in that respect destroy rather than promote uniformity.

The Committee deemed it prudent to enlarge the time for the proposed system to take effect to a date somewhat later than the date proposed in the Bill submitted, adopting for America about the average time deemed necessary by other nations. It is therefore recommended that the time for adoption in the Departments and operations of the Government, except in the completion of the survey of the public lands, be fixed for July 1, 1898, and that the adoption of the metric system for use in the nation at large be fixed as coincident with the dawn of the twentieth century, and that date be accordingly changed to January 1, 1901, the first day of the new century.

The Bill reads as follows:—

"A Bill to fix the standard of weights and measures by the adoption of the metric system of weights and measures.

"*Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled*, That from and after the first day of July, eighteen hundred and ninety-eight, all the Departments of the Government of the United States, in transaction of all business requiring the use of weight and measurement, except in completing the survey of the public lands, shall employ and use only the weights and measures of the metric system.

"Sec. 2. That from and after the first day of January, nineteen hundred and one, the metric system of weights and measures shall be the only legal system of weights and measures recognised in the United States.

"Sec. 3. That the metric system of weights and measures herein referred to is that in which the ultimate standard of mass or weight is the international kilogram of the International Bureau of Weights and Measures, established in accordance with the convention of May twentieth, eighteen hundred and seventy-five, and the ultimate standard of length is the international metre of the same bureau, the national prototypes of which are kilogram numbered twenty and metre numbered twenty-seven, preserved in the archives of the office of standard weights and measures.

"Sec. 4. That the tables in the schedules annexed to the Bill authorising the use of the metric system of weights and measures passed July twenty-eighth, eighteen hundred and sixty-six, shall be the tables of equivalents which may be lawfully used for computing, determining and expressing the customary weights and measures in the weights and measures of the metric system."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The first Smith's Prize is awarded to Mr. W. S. Adie, bracketed Senior Wrangler 1894; the second is divided between Mr. A. Y. G. Campbell, bracketed ninth Wrangler, and Mr. F. W. Lawrence, bracketed fourth Wrangler in the same year. All the prizemen are members of Trinity College.

Prof. Newton, F.R.S., has been reappointed one of the managers of the Balfour Studentships in Animal Morphology until June 1901.

The School of Medicine of the University of Toronto has been placed on the list of Colonial Schools recognised by the Special Board for Medicine.

The Council of the Senate recommend for affiliation to the University the Roman Catholic College of St. Edmund's, Ware, the successor since 1793 of the former English College at Douai.

On account of the increasing length of the practical examinations for the Natural Sciences Tripos, the Medical Board propose that the examinations for M.B. shall in future take place at a later date in the Michaelmas and Easter Terms. It is noted that a number of medical students are following with advantage the course for the ordinary B.A. degree, and a rearrangement of the dates of the examinations has become necessary to meet their case.

The next examination for the diploma in Agriculture will begin on July 6, and last a week.

SIR WILLIAM PRIESTLEY, the distinguished physician, has been elected parliamentary representative of the Universities of Edinburgh and St. Andrews.

THE City and Guilds of London Institute is inviting applications for the Professorship of Mechanical Engineering and Applied Mathematics at the Technical College, Finsbury, rendered vacant by the appointment of Prof. John Perry, F.R.S., to a Professorship at the Royal College of Science. Applications for the appointment should be addressed to the Honorary Secretary at the office of the Institute, Gresham College, E.C.

THE following are among recent appointments:—Dr. Zuber, Privatdocent in Geology in Lemberg University, to be Extraordinary Professor; Dr. Henking, Privatdocent in Zoology in Göttingen University, to be Extraordinary Professor; Dr. Oertel to be Observer in the Observatory at Munich; Dr. Ludwig Kathariner to be Professor of Zoology and Comparative Anatomy in the University of Fribourg; Prof. Dr. Buchner to be Extraordinary Professor of Chemistry at Tübingen; Dr. Albert Fleischmann to be Director of the Zoological Institute at Erlangen; Dr. George Rorig to be Extraordinary Professor of Zoology in Konigsberg University.

MR. JAMES G. LAWN, Instructor in Mine Surveying at the Royal College of Science, London, has been appointed Professor of Mining at the South African School of Mines. The School was started some years ago, but it is undergoing reorganisation. It is proposed that the course of instruction shall extend over four years; the first two years—in which scientific instruction will be given—being spent at the South African College, Cape Town. The third year will be spent at Kimberley, where theoretical and practical instruction in mining will be given. The fourth year will be chiefly taken up with practical work at Johannesburg. The Cape of Good Hope University is to be asked to establish a Mining degree, the final examinations for which the students would attend at the end of their fourth year. So far only the preliminary scientific instruction has been given, and Mr. Lawn is going out to organise and initiate the instruction to be given in the third and fourth years of the course. The salary is £800 a year.

FULL recognition is being given to the scientific attainments of women in America. We learn from *Science* that at Bryn Mawr College Miss F. Cook has been appointed Fellow in mathematics; Miss F. Lowwater, in physics, and Miss C. Fairbanks, in chemistry.

Science records the following gifts to education and research in America. Mrs. Lydia Bradley, of Peoria, Ill., has made known her attention of giving 1,000,000 dols. for a polytechnic institute in Peoria.—A Boston citizen, whose name is withheld, has given 100,000 dols. to establish a chair of Comparative Pathology in the medical school of Harvard University.—Mrs. J. S. T. Stranahan, of Brooklyn, has given 5000 dols. to the building fund of Barnard College.—The Catholic University has received 5000 dols. by the will of the Rev. Father Dougherty, of Honesdale, Pa.—It is expected that Mayor Strong will approve the Bill authorising the Board of Estimate and Apportionment to give the College of the City of New York 175,000 dols. a year instead of 150,000 dols., the amount it has received for several years.

AT the general meeting of Convocation of the University of London, held on Tuesday, it was resolved—"That some means should be devised for a more thorough preliminary investigation

than has hitherto been usual of the mathematical questions proposed to be set in the University examinations." The following resolutions were also carried. (1) That a special Committee of thirteen members, including the Chairman of Convocation, be nominated to prepare for presentation to any Statutory Commission which may be appointed a memorandum of points in the scheme of the Royal Commission in which modification is desirable, and with power to confer with such said Statutory Commission, and with the Senate or any Committee thereof. (2) That this special Committee consist of the following members :—The Chairman of Convocation, Dr. Allchin, Dr. Benson, Mr. Bompas, Mr. Stanley Boyd, Dr. Cave. Mr. Cozens-Hardy, Mr. Thiselton-Dyer, Dr. Heber Hart, Dr. Napier, Mr. Blake Odgers, Dr. Sansom, Prof. S. P. Thompson. (3) That the new and enlarged special Committee recommended for appointment in the report of the special Committee on the memorandum to be presented to such said Statutory Commission should have full powers, if it thinks fit, to prepare amendments to the London University Commission Bill and to have them proposed on behalf of Convocation in either House of Parliament.

AT a special meeting of the Technical Instruction Committee of the Cheshire County Council the following resolutions were adopted, and instructions given for them to be forwarded to the President and Vice-President of the Council.

(1) "That in the opinion of this Committee the Education Bill of this Session, as printed, will have the effect, by adding new subjects (not technical nor manual) for assistance out of the Customs and Excise grant, of making it impossible for the successors of this Committee, without recourse to a rate in aid, to continue the maintenance grants to those Science and Art Committees which their predecessors have, in good faith, on the assurance of her Majesty's Ministers in the past that the grant or its equivalent would not be withdrawn, fostered, or created. That the financial clauses of the Bill, confirming only a rate of one penny in the pound, in addition to the local taxation (Customs and Excise) grant, are inadequate for the work of secondary and technical education it is proposed the new Education Committee shall undertake."

(2) "That this Committee would respectfully urge upon her Majesty's Government that a County Council may have the option of nominating two school committees, one an elementary school committee, and the other a secondary school committee, with a view to secure for service in each committee members specially qualified for the work of each grade who would not have leisure time to attend to the two combined, and ventures to express a hope that for the purpose of education other than elementary the cost thereof may be wholly borne by the Imperial Exchequer, or, failing that, the Education Committee may have the benefit of at least a rate of *2d.* in the pound."

(3) "That, in the opinion of this Committee, Clause II., Subsection 3, relating to the performance by the education authority of the work of the numerous school attendance committees in the county, is impracticable, and cannot be undertaken by the education authority."

SCIENTIFIC SERIALS.

American Journal of Science, April.—The morphology of *Triarthrus*, by C. E. Beecher. Most of the recent advances in the knowledge of trilobite structure have come from the study of Triarthrus. Much time was spent by the author in carefully working out the numerous specimens from the abundant material in the Yale Museum. Altogether upwards of five hundred individuals with appendages more or less complete have been investigated; and at the present time all the important exoskeletal features have been seen and described. The appendages of *Triarthrus* are exceptionally long. It must have been a sort of "Daddy Long-legs" among the Trilobites, as *Scutigera* is among the Myriapoda. The delicacy of the appendages and ventral membrane of trilobites and their rarity of preservation are sufficient demonstration that these portions of the outer integument were of extreme thinness, and therefore perfectly capable of performing the function of respiration. The paper is accompanied by a plate showing a dorsal and a ventral view of a specimen fully restored.—Climatic zones in Jurassic times, by A. E. Ortmann. The author proves that the argument given by Neumayr for the non-existence or non-action of topographical differences upon the distribution of the Jurassic faunas is a complete failure. Only one point may be granted, that a separation by land was not present in an extensive manner. On the other hand, it is highly probable that on the one side differences of depth of the seas, on the other differences of facies, are the laws governing the faunistic differences. The first cause applies especially to the distinction of the Mediterranean and Middle-European provinces, the second to that of the Middle-European and Russian (Boreal) provinces.—Metamorphism of a gabbro occurring in St. Lawrence County, N.Y., by C. H. Smith, junr. The extreme effect of metamorphism on this gabbro has been to produce complete recrystallisation, yielding a granulitic structure. This metamorphism takes place in three stages. The first is marked by the formation of scapolite and some scaly hornblende, with little or no sign of crushing, the probable agents of change being pressure, heat, and solutions. In the second stage the effects of crushing are pronounced. All of the constituents are granulated, and the rock becomes more or less gneissoid. At the same time the scaly hornblende increases in quantity, seeming to reach its maximum in this phase of the rock. Finally, in the third stage, the rock undergoes complete recrystallisation, the newly-formed constituents being arranged normal to the pressure that has crushed the rock, and thus producing a pronounced gneissoid structure.—An occurrence of free gold in granite, by G. P. Merrill. A piece of quartz described as "gold ore, Sonora, Mexico," was found to be not superficially impregnated with gold, but to contain flecks of free gold throughout its substance. There is no other way of accounting for it other than by considering it a true constituent of the rock, crystallised from the original magma. It is completely embedded in the clear grassy quartz and unfissured felspars. No pyrite or other sulphides could be detected. This is believed to be a unique occurrence.

Wiedemann's Annalen der Physik und Chemie, No. 4.—On the nature of the X-rays, by D. A. Goldhammer. The author believes the X-rays to be not longitudinal light waves, but ultra-violet rays of extreme shortness. The absence of refraction would be quite consistent with this view, since in several theories of dispersion the index of refraction for infinitely short waves is unity. The absence of reflection would be due to the smallness of the waves compared with the unevenness of ordinary polished surfaces. This also explains the absence of polarisation. As regards the variation of absorption with the density simply, this is analogous to the absorption of light by aniline and other solutions, which simply depends upon their concentration. The author gives no reason against these rays consisting of longitudinal vibrations.—On the determination of overtones, by C. Stumpf. Careful investigations show that wherever overtones may influence the result of an experiment, the source of sound must always be specially tested as regards its composition, and that theoretical proofs of the simplicity of a tone are often misleading. Wherever simple tones are to be produced, the sound must be as faint as possible, or the overtones must be excluded by interference.—On the origin of contact electricity, by C. Christiansen. To establish a difference of potential between mercury and either zinc, cadmium, lead, or tin amalgam, the presence of oxygen is essential. Further experiments were made with hydrochloric and sulphurous acids, carbon bisulphide and nitrous oxide. Hydrochloric acids gave a polarisation effect with all the amalgams for which it was found in the case of oxygen, and for copper in addition. SO_2 gave effects with zinc and cadmium. The other gases gave no effect.—Polarisation and resistance of a galvanic cell, by Franz Streintz. The author shows that the determination of galvanic polarisation in an electrolytic cell in a closed circuit is an impossibility, since the "resistance" of the cell is an unknown function of the current strength.—The iron sphere in a homogeneous magnetic field, by O. Grotrian. By induction experiments made with coils of wire laid over an iron sphere so as to cut off segments of various sizes the author shows that the sphere is evenly magnetised throughout its substance, as predicted by theory. The result is not affected by the direction of "grain" of wrought iron.—Diminution of the intensity of sound with the distance, by K. L. Schaefer. Sound does not diminish in intensity strictly with the square of the distance, but at first more slowly, and then more rapidly. This was proved by means of a telephone attached to a clock and brought to different degrees of sensitiveness.

Memoirs (*Zapiski*) *of the Caucasian Branch of the Russian Geographical Society*, vol. xviii., Tiflis, 1896.—Review of the atmospheric sediments fallen in Caucasia during the spring and summer of 1894, by A. Woznesensky, with four maps.—A journey to the mountain region of the district Tchernomorsk, by N. Albof, with a map of the district, 6·7 miles to the inch. The author has visited, for botanical purposes, some of the least-known valleys of the region, and now gives the diary of his journey.—Studies in the geographical botany of Western Transcaucasia, by the same author. The article is full of valuable data. Several interesting finds are mentioned, such as the new species *Amphoricapus elegans*, and a *Campanula*, which so much exceeds all known species of the same genus by its beauty, that M. Albof proposes for it the name of *Campanula regina*, and remarks that its general shape so much differs from all other now living *Campanula* species that it must be, without doubt, a remainder from a foregone geological flora.—On the Kumyks, an anthropological sketch, by J. Pantukhof.—The Pshaves and their land, by M. Khizanachwili.—A journey to the central part of the land of the Chechenes, by Mdme. A. Rossikof, with a map, three miles to the inch, of this very little part of the main ridge.—A statistical description of the governments of Baku and Kars, from the "Caucasian Calendar."—The state of the glaciers on the northern slope of the Caucasus, by K. Rossikof, being the results of the measurements of the motion of several glaciers in 1893 and 1894; and on the present state of the desiccating lakes of the northern slopes of the Caucasus, by the same author. The same volume contains, as a supplement, a most welcome atlas of ethnographical maps of Transcaucasia, drawn by the Secretary of the Society, E. Kondratenko. The maps are the result of many years' work. The classification of the more than sixty different stems which inhabit Transcaucasia is the result of the remarkable works of Baron Uslar and his follower, M. Zagursky; and the numerical data as to the numbers of inhabitants belonging to each stem are obtained from a census made in the years 1886–1891. The maps, on the scale of thirteen miles to the inch, are seven in number, and represent the governments of Tiflis, Kutais, Baku, Elizabethpol, Daghestan, Erivan, and Kars. The limits of each village community are indicated, and the nationality which prevails in each village is shown in different colours; while, on the borders of each map, special coloured diagrams give the ethnographical composition and the numbers of each nationality for each town and district, as well as for the whole government, so that one sees at a glance their numerical proportions. Full tables of figures are given by M. E. Kondratenko in the text of the *Zapiski*. The value of this work is enhanced by an ethnographical map of Turkish Armenia and Kurdistan, published in the same volume. It is based upon V. Cuinet's statistics, given in his work, "La Turquie d'Asie," and shows in different colours the percentage of Turks and Armenians in each *kaza*, or sub-district.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 30.—"The Total Eclipse of the Sun, April 16, 1893. Report and Discussion of the Observations relating to Solar Physics." By J. Norman Lockyer, C.B., F.R.S.

The memoir first gives reports by Mr. Fowler and Mr. Shackleton as to the circumstances under which photographs of the spectra of the eclipsed sun were taken with prismatic cameras in West Africa and Brazil respectively on April 16, 1893. These are followed by a detailed description of the phenomena recorded, and a discussion of the method employed in dealing with the photographs. The coronal spectrum and the question of its possible variation, and the wave-lengths of the lines recorded in the spectra of the chromosphere and prominences, are next studied.

Finally, the loci of absorption in the sun's atmosphere are considered.

The inquiry into the chemical origins of the chromospheric and prominence lines is reserved for a subsequent memoir.

The general conclusions which have been arrived at are as follows:—

(1) With the prismatic camera, photographs may be obtained with short exposures, so that the phenomena can be recorded at short intervals during the eclipse.

(2) The most intense images of the prominences are produced by the H and K radiations of calcium. Those depicted by the rays of hydrogen and helium are less intense, and do not reach to so great a height.

(3) The forms of the prominences photographed in monochromatic light (H and K), during the eclipse of 1893, do not differ sensibly from those photographed at the same time with the coronagraph.

(4) The undoubted spectrum of the corona in 1893 consisted of eight rings, including that due to 1474 K. The evidence that these belong to the corona is absolutely conclusive. It is probable that they are only represented by feeble lines in the Fraunhofer spectrum, if present at all.

(5) All the coronal rings recorded were most intense in the brightest coronal regions, near the sun's equator, as depicted by the coronagraph.

(6) The strongest coronal line, 1474 K, is not represented in the spectrum of the chromosphere and prominences, while H and K do not appear in the spectrum of the corona, although they are the most intense radiations in the prominences.

(7) A comparison of the results with those obtained in previous eclipses confirms the idea that 1474 K is brighter at the maximum than at the minimum sun-spot period.

(8) Hydrogen rings were not photographed in the coronal spectrum of 1893.

(9) D_3 was absent from the coronal spectrum of 1893, and reasons are given which suggest that its recorded appearance in 1882 was simply a photographic effect due to the unequal sensitiveness of the isochromatic plate employed.

(10) There is distinct evidence of periodic changes of the continuous spectrum of the corona.

(11) Many lines hitherto unrecorded in the chromosphere and prominences were photographed by the prismatic cameras.

(12) The preliminary investigation of the chemical origins of the chromosphere and prominence lines enables us to state generally that the chief lines are due to calcium, hydrogen, helium, strontium, iron, magnesium, manganese, barium, chromium, and aluminium. None of the lines appear to be due to nickel, cobalt, cadmium, tin, zinc, silicon, or carbon.

(13) The spectra of the chromosphere and prominences become more complex as the photosphere is approached.

(14) In passing from the chromosphere to the prominences, some lines become relatively brighter but others dimmer. The same line sometimes behaves differently in this respect in different prominences.

(15) The prominences must be fed from the outer parts of the solar atmosphere, since their spectra show lines which are absent from the spectrum of the chromosphere.

(16) The absence of the Fraunhofer lines from the integrated spectra of the solar surroundings and uneclipsed photosphere shortly after totality need not necessarily imply the existence of a reversing layer.

(17) The spectrum of the base of the sun's atmosphere, as recorded by the prismatic camera, contains only a small number of lines as compared with the Fraunhofer spectrum. Some of the strongest bright lines in the spectrum of the chromosphere are not represented by dark lines in the Fraunhofer spectrum, and some of the most intense Fraunhofer lines were not seen bright in the spectrum of the chromosphere. The so-called "reversing layer" is therefore incompetent to produce the Fraunhofer spectrum by its absorption.

(18) Some of the Fraunhofer lines are produced by absorption taking place in the chromosphere, while others are produced by absorption at higher levels.

(19) The eclipse work strengthens the view that chemical substances are dissociated at solar temperatures.

May 7.—"On the Occurrence of the Element Gallium in the Clay-Ironstone of the Cleveland District of Yorkshire." By Prof. W. N. Hartley, F.R.S., and Hugh Ramage.

The evidence of the existence of gallium in the ore and in the metal rests on the measurements of the wave-lengths of the lines in a large number of photographed spectra and upon the relative strengths of the lines in the different materials examined and in the precipitates obtained therefrom.

Examples are given showing the nature of this evidence.

Chemical Society, April 23.—Mr. A. G. V. Harcourt, President, in the chair.—The following papers were read:—The constitution of the cereal celluloses, by C. F. Cross, E. J. Bevan, and C. Smith. The cereal celluloses may be resolved by acids into a residue of normal cellulose and a soluble furfuroid con-

stituent; the latter seems to be a pentosemonoformal of the constitution $C_5H_8O_3\left\langle\begin{matrix}O\\O\end{matrix}\right\rangle CH_2$.—On a new compound of cobalt and a rapid method of detecting cobalt in presence of nickel, by R. G. Durrant. On adding excess of an alkali bicarbonate, and then hydrogen peroxide, to a solution of cobalt salt, a green solution, which appears to contain a salt of cobaltic acid H_2CoO_4, is obtained.—Ethereal salts of optically active malic and lactic acids, by T. Purdie and S. Williamson. The specific rotations of the ethereal salts of active lactic and malic acids vary with the method of preparation of the substances; the variations in rotatory power do not seem to be altogether due to the occurrence of partial racemisation.—Metadichlorobenzene, by F. D. Chattaway and R. C. T. Evans. A convenient method of preparing large quantities of 1 : 3-dichlorobenzene from acetanilide is described.—On the temperature of certain flames, by W. N. Hartley.—The determination of the composition of a white sou by a method of spectrum analysis, by W. N. Hartley. A photograph of the spectrum of a white sou coined during the French Revolution of 1798 was taken, and by comparison with the quantitative spectra of the constituent metals, the composition of the coin was determined within certain limits; alloys, the compositions of which varied within these limits, were then made, and their spark spectra photographed. An alloy, consisting of 13·93 per cent. of lead, 72·35 of copper, 0·85 of iron, and 12·70 per cent. of zinc, was ultimately obtained, which gave a spark spectrum identical with that of the sou; the coin consequently has the above composition.—Halogen additive products of substituted thiosinnamines, by A. E. Dixon.—Acidic thiocarbimides, thioureas, and ureas, by A. E. Dixon.—Apparatus for the detection of boric acid, by W. M. Doherty. A method is given for the detection of boric acid in milk, wine, or other substance, depending on the fact that when boric acid is heated in a current of coal-gas which is then burnt, a characteristic colouration is imparted to the flame.

Zoological Society, April 29.—Sir William H. Flower, K.C.B., F.R.S., President, in the chair.—After the Auditors' Report had been read, and other preliminary business had been transacted, the Report of the Council on the proceedings of the Society during the year 1895 was read by Mr. P. L. Sclater, F.R.S., the Secretary. The total receipts of the Society for 1895 amounted to £26,958 9*s*. 1*d*., showing an increase of £1851 8*s*. 6*d*. as compared with the previous year. This increase was attributable to the prevalence of fine weather during the summer and autumn of 1895, and also to the acquisition of a giraffe, and several other specially interesting additions to the Society's menagerie. A new edition of the list of animals in the Society's collection, of which the last (the eighth) was published in 1883, has been prepared under the direction of the Secretary. It contains a list of all the specimens of vertebrated animals that had been received by the Society during the past twelve years. This volume is now going through the press, and will, it is hoped, be ready for issue before the close of the present year. The number of visitors to the gardens in 1895 was 665,326, which was greater than it had been in any year during the past ten years. The corresponding number in 1894 had been 625,538. The number of animals in the Society's collection on December 31 last was 2369, of which 768 were mammals, 1267 birds, and 334 reptiles. Amongst the additions made during the past year, twelve were specially commented upon as of remarkable interest, and in most cases new to the Society's collection. Amongst these were a male lion from Somali-land (presented by her Majesty the Queen), a female South African giraffe, a pair of brindled gnus, a pair of sable antelopes, a Brazilian three-banded armadillo, a male Panolia deer from Southern China, an Alexandra parrakeet from the interior of Australia, a frilled lizard from Western Australia, a martial hawk-eagle from British East Africa, and two examples of Forsten's lorrikeet. The Report having been adopted, the meeting proceeded to elect the new Members of Council and the Officers for the ensuing year. The usual ballot having been taken, it was announced that General the Hon. Sir Percy Feilding, K.C.B., Prof. Alfred Newton, F.R.S., Sir Thomas Paine, Mr. E. Lort Phillips, and the Lord Walsingham, F.R.S., had been elected into the Council in the place of the retiring Members; and that Sir William H. Flower had been re-elected President, Mr. Charles Drummond Treasurer, and Mr. P. L. Sclater Secretary to the Society for the ensuing year.

PARIS.

Academy of Sciences, May 4.—M. A. Cornu in the chair.—On the theory of gases, by M. J. Bertrand. A critical examination of the well-known formula of Maxwell for the relation between the velocities of the gaseous molecules and their components in any arbitrarily chosen direction. This formula is described as necessarily absurd, since it gives an apparent solution of a problem insoluble from its very nature.—On the constitution and history of the lunar surface, by MM Lœwy and Puiseux. The results of a study of a new serie of lunar photographs tend to show that it is unnecessary to assume the action of natural forces other than those now at work on the earth to explain the condition of the surface of the moon.—On the birds and butterflies observed in the centre of an intertropical tempest, by M. H. Faye. The author shows that the occurrence of birds and insects in the calm centre of a cyclone, a fact frequently observed, is in full accord with his theory of storms.—Concerning hematozoa in marsh-fever, by M. A. Laveran. Although the presence of amœboid parasites in the blood during marsh-fever is now well established, there is hardly any ground for the assumption of distinct species peculiar to each variety of the disease, one for tertiary ague, another for quaternary ague, and a third giving rise to irregular fevers. This assertion is supported both by the microscopical study of the parasite and by the clinical study of the disease.—Observations of the new Swift comet (*b* 1896 = 1896, April 13), made at the Observatory of Paris by M. G. Bigourdan.—On the approximate development of the perturbation function in the case of inequalities of a high order, by M. Maurice Hamy.—A property of movements on a surface, by M. Hadamard.—On the absorption of light by media possessing rotatory power, by M. E. Carvallo.—Electrostatic deviation of the kathode rays, by M. G. Jaumann. A reply to some criticisms and suggestions of M. Poincaré. By immersing the vacuum tube in oil forming the anode, the rays are much reduced in intensity, and in this state are strongly deviated by electrostatic forces.—Observations on the preceding communication, by M. Poincaré. The suggestion of M. Jaumann that inside a Crookes' tube the lines of force are rectilinear, is directly opposed to the conclusion drawn by Hertz from his experiments.—Apparatus for measuring currents of high frequency, by MM. G. Goiffe and E. Meylan.—Reply to some observations of M. Aug. Righi, by MM. L. Benoist and D. Hurmuzescu.—On the relation between the maximum production of the X-rays, the degree of vacuum and the form of the tubes, by MM. Victor Chabaud and D. Hurmuzescu. The pressure giving the maximum result varies with the shape of the tube. A form of tube is figured giving a choice of two anodes from which excellent results were obtained.—Radiography; some applications to the physiology of motion, by MM. Imbert and Bertin-Sans.—On a new method of preparing synthetically urea, and its symmetrical derivatives, by M. P. Cazeneuve. The carbonate of guaiacol, now easily obtained commercially, on treatment with alcoholic ammonia or amines, gives the corresponding urea in nearly theoretical yield.—Transformation of tariric and stearoleic acids into stearic acid, by M. A. Arnaud. This reduction, which is not effected by sodium amalgam, takes place readily with hydriodic acid and amorphous phosphorus.—On the presence, in the *Monotropa Hypopithys*, of a glucoside of methyl-salicylic ether, and on the hydrolysing ferment of this glucoside, by M. E. Bourquelot.—On maize, by M. Balland. Some analyses showing the superior nutritive power of Indian corn as compared with wheat.—On zeolites and the substitution of the water they contain by other substances, by M. G. Friedel. The dehydrated mineral readily takes up sulphuretted hydrogen, carbonic acid, hydrogen, and even atmospheric air, the last to such an extent as to render it impossible to determine the amount of water by loss or ignition.—On the Annelids at great depths in the Bay of Biscay, by M. Louis Roule. The results of soundings from the *Caudan* in April 1895.—On the first cause of potato-scab, by M. E. Roze.—On the age of the ophitic eruption of Algeria, by M. L. Gentil.—On a method of photographing the retina, by M. V. Guinkoff.—The fermentation of uric acid by micro-organisms, by M. E. Gerard. In the experiments cited the uric acid was split up into urea and ammonium carbonate.—Researches on the serotherapy of urinary infection, by MM. J. Albarran and E. Morny.—On the relations between the composition of the blood, the quantity of hæmoglobin, and the general state of the organism, by M. P. Lafon.—Projection of a thermometer column on a sensitive plate, by means of the Röntgen rays, by M. H. Bentéjac.

AMSTERDAM.

Royal Academy of Sciences, March 28.—Prof. van de Sande Bakhuyzen in the chair.—Prof. Kamerlingh Onnes exhibited a series of extremely clear photographs, obtained with Röntgen rays by Prof. Haga at Groningen. The exposure did not last longer than one minute.—Prof. Kamerlingh Onnes presented, on behalf of Dr. Siertsema, a paper to be published in the report of the meeting, on measurements of magnetic rotation dispersion in gases.—Prof. Franchimont on the action of nitric acid upon methyl and dimethyl amides at the ordinary temperature. The author showed to what extent the action depends upon the acid-residue of the amides, and proved that the same rules also hold good for the piperidides. For this purpose the author, in conjunction with Dr. van Erp, examined oxal-piperide, which enters into an unstable compound with nitric acid, but is not otherwise influenced, resembling in this tetramethyloxamide, previously studied in conjunction with Mr. Rouffaer. The author and Dr. Taverne examined (1) trichloracetpiperidide, a beautifully crystallised substance, fusing at 45°; (2) benzolsulphonepiperidide; (3) picrylpiperidide; and, as they had expected, they found that the first was not influenced, the second yielded nitropiperidine, and the third a picryldehydronitropiperidide as a red, beautifully crystallised body, fusing at 95°.—Prof. Franchimont further treated of the action of alkalies upon nitramines, in examining which action Dr. van Erp found that a great quantity of nitrous acid is formed. With some nitramines, as nitrohydantoin, nitromethylhydantoin, nitrolacetylureum, nitroamidoacetamide, when treated with baryta-water, the formation of nitrous acid already takes place at a low temperature; others, as nitroacetonyl-urea, ethylenedinitro-urea, dinitroglycoluril, &c., behave differently.

SOCIOLOGY.

The Principles of Sociology; an Analysis of the Phenomena of Association and of Social Organisation. By Franklin Henry Giddings, M.A., Professor of Sociology in Columbia University in the City of New York. Pp. xvi + 476. (New York and London: Macmillan and Co., 1896.)

WITH extensive learning and a good deal of original speculation, Prof. Giddings has written a very useful general introduction to sociology. The scope and nature of this recently established science are not yet well understood, and hitherto it has been difficult to refer to any one book from which they could be learnt; for Comte is out of date; Mr. Spencer's great work is still incomplete, though already rather terrifying in its proportions; and the greater part of the information obtainable on the subject must be sought in innumerable monographs on primitive law, marriage, religion, art, in volumes, essays, and the journals of learned societies. In the present volume, however, the most interesting lines of sociological inquiry are indicated, and the best ascertained results are collected, critically examined, and scientifically arranged within a moderate compass.

The preliminary discussions of the province of sociology and its logical methods of research, attest the care with which the author has prepared for his task by studying the physical sciences. Some passages in chapter iii., on method, may perhaps be considered fanciful, but they do not prevent his coming to sound conclusions.

The second book is descriptive and classificatory, dealing with the facts of population, its growth, diffusion, and localisation; with the social mind, its traditions and standards (there is no mysticism about it); with social composition according to tribes and nations, and social constitution or organisation for government, industry, &c.

Then follows an investigation of the history of society; the place of man's origin, the origin of races, and of the great groups of ideas that constitute law, art, religion, &c.; the growth of the tribe in its metronymic and patronymic forms, and finally of civilised peoples.

The fourth and last book formulates the ultimate causes and laws of social evolution, as objectively a conflict of physical forces tending to equilibrium, and subjectively the production of personality and of forms of association that partly result from and partly determine the characters of human beings.

The treatment throughout is scientific: it is well proportioned, and fully illustrated from history and anthropology. If fault must be found, it may perhaps be said that there are some needless pages in Book iii. chapter ii., where Prof. Giddings tries to frame hypotheses as to the birthplace of our race and the origin of races; inquiries which, in the present state of our knowledge, can only lead to a submerging of the halfpennyworth of fact by floods of speculation. And the first chapter of Book iv., on the physical interpretation of the social process, should be much expanded and illustrated. As it stands, it is intelligible only to trained readers.

There are also, of course, in so comprehensive a work, a good many disputable positions, two of which may be selected for special comment. In Book iii. chapter iv., on demogenic association, Prof. Giddings distinguishes three stages in the growth of civilised societies: (1) the Military-Religious, (2) the Liberal-Legal, (3) the Economic-Ethical. Noticing previous attempts to demarcate such epochs of progress, he complains that Hegel's doctrine of successive steps in the acquisition of freedom or self-realisation, and Comte's "law of the three states," are alike one-sidedly subjective, and fail to give any account of the structural changes of society. Mr. Spencer, again, recognises only two stages, the military and industrial, corresponding on the whole to (1) and (3) of the author's own divisions. But this criticism rests upon an oversight with regard to Comte. Turning to Comte's chapters on sociology, it will be seen that the indication of the military and industrial stages of society is due to him. He regards them as naturally coinciding respectively with the theological and positive stages of explanation; and, further, he indicates an intermediate phase of social organisation similar to Prof. Giddings' (2), the Liberal-Legal, and naturally coinciding with the age of metaphysical explanation. This intermediate stage, however, in both organisation and explanation, he treats as essentially transitional and as wanting the relative stability of militarism and industrialism. How comparatively unimportant it is in universal history (though important to us who have not yet escaped from it), may be seen at p. 301 of this work, where its extent in modern history is indicated as dating from the Renaissance: 500 years! Merely a list of revolutions! Mr. Spencer seems to be fully justified in not giving to this unstable period the rank of those forms of culture of which one endured, and the other may endure, for thousands of generations. As for Comte, he has been adulated and repudiated enough, and would now gain much by getting bare justice.

Again, in his first chapter, Prof. Giddings, after observing that sociology, having for its object phenomena which, on the one hand, may be viewed as a redistribution of matter and motion, and, on the other, as effects of knowledge and volition, must seek its explanations in the co-operation of physical and psychical causes, according to laws subjective and objective, coinciding and verifying one another, goes on to say that he accepts Mr. Spencer's objective interpretation of the social process, as a "formal evolution through the equilibration of energy," but that an adequate conception of the process on the subjective side is still wanting. He then offers to supply the want thus:—

"The original and elementary subjective fact in society is *the consciousness of kind*. By this term I mean a state of consciousness in which any being, whether low or high in the scale of life, recognises another conscious being as of like kind with itself" (p. 17.)

But surely this cannot be the fact he is in quest of; for the "consciousness of kind" is mainly a fact of perception; whereas what he needs is something corresponding to the physical energy that moulds societies considered objectively, and this subjectively can only be a fact of volition. The fact that is wanted, moreover, must not only correspond with the physical cause of the

social process, but also in its consequences with the physical result, namely, the establishment of a moving equilibrium. Both these requirements are met by our old-fashioned friend utility: desires are the psychical causes; and the maximum satisfaction with the nearest approach to equal conditions, may one day correspond with the nearest approach to equilibrium. No doubt the consciousness of kind is a condition of the development of social life, as in the phenomena of sympathy and (to take the social process pretty early) in bisexual generation. But it may be presumed that the consciousness of kind, sympathy, and bisexual generation are all subordinate to objective utility (survival), or they could never have existed at all; and the connection of subjective with objective utility through the laws of pleasure and pain is well known.

It is a pleasure to add that this unpromising theory at the outset of the book does very little harm in the sequel, and by no means prevents the author's knowledge and penetration from producing very interesting and instructive work.

CARVETH READ.

COCOA CONNOTATIONS.

Cocoa: All about It. By Historicus. Pp. 99. (London: Sampson Low, Marston, and Co., Limited, 1896.)

IN this book the author has managed to justify his title, for if he has not reproduced *all* that has been written and said about cocoa, he has strung together a large number of extracts from early records referring to its history, cultivation, and uses. About one-half the book is devoted to these subjects, and the remainder to the manufacture, the value of cocoa as food, its adulterations, and finally a few pages to the subject of vanilla as a flavouring agent to chocolate.

The chief interest of the book, however, will be found in the first two chapters, namely, "The History and Cultivation of the Cocoa Plant," and "History of the Use of Cocoa"; and we say this advisedly, for the author has apparently been at some pains in collating these extracts, which do not appear in every essay on cocoa, while cocoa manufacture, its value as food, and its adulterations have been the subject of many themes since it has become such a popular and wide-spreading beverage. It may be a surprise to some persons to know that though cocoa is a comparatively modern drink with us, it was well known to the early Mexicans. The author says: "Our knowledge of cocoa as an article of diet dates from the discovery of the Western World in 1494 by Columbus, who, we are told, took home with him samples of the article; and from the subjugation of Mexico by Cortez in 1521. History informs us that the Spaniards were the first who tasted chocolate, which was part of their spoil in the conquest of Mexico." An additional tribute to the early use of cocoa is given from a MS. in the British Museum, "written in Old English characters and entitled 'A Voyage to the West Indies and New Spain' (Yucatan) made by John Chilton in the year 1560. He says: 'So we were provided of victualls till we came where Townes were in the province of Soconusco, where groweth Cacau, w^{ch} the Christianes carrye from thence unto Nova Hispaniola because y^{t} will not grow in a cold countrye. . . . Their chiefest marchandize is Cacau.'" It is not a little remarkable that one of the finest qualities of cocoa at the present time is produced at Soconusco on the coast of Guatemala. The following extract from an account of the rise and growth of the West Indies, written in 1690, is given as showing an early attempt and failure by the English to cultivate cocoa.

"Cocoa," it is said, "is now a commodity to be regarded in our colonies, though at first it was the principal invitation to the peopling of Jamaica, for whose walks the Spaniards left behind them there, when we conquered it, produced such prodigious profit with so little trouble that Sir Thos. Modiford and several others set up their rests to grow wealthy therein, and fell to planting much of it, which the Spanish slaves had always foretold would never thrive, and so it happened, for though it promised fair, and throve finely for five or six years, yet still at that age when so long hopes and cares had been wasted upon it, withered and died away by some unaccountable cause, though they imputed it to a black-worm or grub which they found clinging to its roots, and did it not almost constantly die before, would come into perfection in fifteen years' growth and last till thirty, thereby becoming the most profitable tree in the world, there having been £200 sterling made in one year of an acre of it. But the old trees being gone by age, and few new thriving as the Spanish negroes foretold, little or none now is produced worthy the care and pains in planting and expecting it. Those slaves gave a superstitious reason for its not thriving, many religious rites being performed at its planting by the Spaniards, which these slaves were not permitted to see. But it is probable that where a nation, as they, removed the art of making cochineal and curing vanilloes into their island provinces, which were the commodities of those islands in the Indians' time, and forbade the opening of any mines in them for fear some maritime nation might be invited to the conquering of them, so they might likewise in their transplanting cocoa from the Caracas and Guatemala conceal wilfully some secret in its planting from their slaves, lest it might teach them to set up for themselves, by being able to produce a commodity of such excellent use for the support of man's life, with which alone and water some persons have been necessitated to live ten weeks together without finding the least diminution of health or strength."

The value in which cocoa is now held as an article of diet, seems from the foregoing paragraph to have been established so long ago as 1690, and its cultivation and consumption still goes on at a marvellous rate. The processes of collecting the pods, extracting the seeds, fermenting, drying, &c., which are more or less generally known, are carefully detailed in the succeeding pages, and it is pointed out that if well cured a cocoa-bean should have the outer skin hard, crisp, and separating easily from the seed inside, which should be firm, bright, and should break readily on pressure, forming the familiar cocoa-nibs of commerce.

On the subject of adulteration, to which cocoa and chocolate lend themselves so readily, and to which so much attention has of late years been drawn, it is curious to note the following paragraph.

"So far back as 1640 in 'A Curious Treatise of the Nature and Quality of Chocolate,' by Antonio Colmenero, which was translated from the Spanish into English, there are some remarkable statements as to the value of chocolate, but the writer recognises the mischief that

adulteration had already done. He says: 'Those who mix maize in the chocolate do very ill, because these grains do beget a very melancholy humour, and those which mix it in this confection, do it only for their profit.'"

The book is illustrated by numerous full-page and smaller illustrations, and is well printed on thick, glazed paper.

THE CHEMISTRY OF ENGINEERING.

Chemistry for Engineers and Manufacturers. A Practical Text-book. By Bertram Blount, F.I.C., F.C.S., and A. G. Bloxam, F.I.C., F.C.S. Volume I. *Chemistry of Engineering, Building, and Metallurgy.* Pp. x + 244. 35 illustrations. (London: Charles Griffin and Co., Limited, 1896.)

THIS book gives a general view of chemical technology, and is intended for the use of engineers, managers of works, and students. It is meant to be read, and not to be treated as a book of reference, and therein differs from the larger works which have already covered the same ground. The authors have confined themselves to explaining the general chemical principles underlying each process, working details and exact descriptions of plant being omitted. Thus the manager of works engaged on a particular process can probably, by perusing this book, find out as much as he desires about any other typical process, although it is perhaps unlikely that he will learn from it much regarding his own business. It is to be regretted that in pursuance of their plan of avoiding all semblance of a book of reference, the authors have in no case indicated where further information can be obtained to supplement their own accounts. The volume is divided into two parts, the first part dealing with the chemistry of engineering and building, and the second with metallurgy. These two parts are very unequal in merit, the first being what it claims to be, a practical treatise, which will doubtless be much appreciated by manufacturers. In this part the accounts given of fuels, and particularly that of gaseous fuel, are useful summaries, and the chapters on steam-raising and on lubricants contain a considerable amount of practical information. These sections will be of value in enabling an owner of machinery or user of power to detect causes of waste, and to realise when saving may be effected by calling in expert assistance.

The part devoted to metallurgy is much less satisfactory. It is evident that, as the attempt has been made to compress an account of the whole art into 104 pages, only the barest outlines of the various processes could be given. Among the unfortunate results of this are that the Patio process for extracting silver from its ores, and the cyanide process for extracting gold, are each dismissed in half a page, though in these cases the chemical actions are complicated and the mechanical arrangements of secondary importance. Such paragraphs serve no useful purpose. There are more mistakes in this part than should have been allowed to creep in, this constituting another point of difference between the two parts. For example, in describing the wet process of copper extraction, the reason for preventing the temperature from rising much above 38° C. is incorrectly stated, the true reason being that the production of ferric salts is favoure by higher temperatures; moreover, a little-used method of keeping down the percentage of ferric salts in the solution is given, while no allusion is made to the ordinary one, viz. the passage of the liquid through a layer of cupriferous pyrites, rich in copper. Again, on p. 214, sulphurous acid is given as one of the agents used to precipitate gold from the solutions obtained in the chlorination process, the fact being that it is only employed to prepare solutions for the passage of sulphuretted hydrogen, which is not mentioned. It may be a hard saying, but there is little doubt that the whole book would have been improved if the part on metallurgy had been left out. Space could then have been found to expand here and there the first part, which, excellent as it is, might thus have been made still more useful.

OUR BOOK SHELF.

Elementary Practical Physics. By William Watson, B.Sc. (London: Longmans, Green, and Co., 1896.)

Elementary Practical Chemistry. By G. S. Newth, F.I.C. (London: Longmans, Green, and Co., 1896.)

WE have long deplored the unfortunate division between theoretical and practical chemistry in many schools and classes, and have been convinced that, alike for educational and utilitarian purposes, physics was a neglected instrument; therefore, very heartily do we welcome the new movement of which these books are a manifestation.

Each volume is described on its title-page as a "laboratory manual for use in organised science schools." Each is written to the new syllabus of the South Kensington Science and Art Department, and each gives excellent directions for setting up (and often for constructing) apparatus, and for taking observations to demonstrate the chief phenomena, and to verify the fundamental laws, of chemistry and physics respectively. In the physics we are glad to see that nearly all the experiments are of a quantitative character; in the chemistry this is far less often the case, partly owing, doubtless, to the nature of the subject. In both works the experiments are judiciously chosen, carefully described, and well illustrated, and in many cases strikingly original.

One criticism of principle may be made. Mr. Newth says: "In a text-book it is almost inevitable that in giving such directions as will lead a student on to the discovery of a fact, the fact itself shall be stated." He may be right in this; but if so, it appears to afford an argument against the use of such text-books in the laboratory at all, for, speaking generally, the most valuable exercise of all for the student is the study of his recorded observations, and the endeavour to deduce therefrom the property or law they demonstrate. Is not the getting up of a proposition of Euclid a smaller intellectual feat than the solution of a "rider"?

Especially does this principle of research appear to be applicable to the laws of elementary physics; but Mr. Watson apparently endorses Mr. Newth's view.

With this reservation, we cordially recommend both these volumes to the notice of teachers of elementary science. From the point of view taken, the work has been well done in both cases, and the books reflect credit alike on authors and publishers. C. H. D.

A Text-Book of the Science and Art of Bread-Making. By William Jago, F.I.C., F.C.S. Pp. 618. (London: Simpkin, Marshall, Hamilton, Kent, and Co., 1895.)

THE practical application of science to the arts and trades has been one of the most notable features of the present century, with the almost universal result of

raising the standard of the articles made, and at the same time of improving the prosperity and health of those who are employed in making them. The volume now before us shows the application of science to the art of bread-making, and a glance at its size and contents will at once show all those who are entering into this business that there is a very large amount of scientific knowledge required to equip a man efficiently to succeed in the keen competition of the present day.

The chemistry of the subject is very fully dealt with, with valuable suggestions for practical work; and we have also a chapter on bacteriology, in which the history of our present knowledge of fermentation is clearly given up to date. Fermentation is, of course, an important process in bread-making, and a chapter on technical researches in this subject is given. The use of the microscope is also pointed out in the examination of different starches, &c. In addition to these principles, which may be said to form the groundwork of the subject, the more practical side also finds a place, such as commercial testing of wheat and flours, different methods of baking, both by machinery and otherwise; and, lastly, there are a few paragraphs on adulterations and the methods for recognising them. Numerous good illustrations are scattered throughout the book. This work will doubtless appeal to all those connected with the business of bread-making, and we imagine it will also find a place on the book-shelves of many medical and other scientific men.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Koch's Gelatine Process for the Examination of Drinking Water.

DR. EDWARD FRANKLAND, in a discourse delivered at the Royal Institution on February 21 (see NATURE, April 30), paid a just tribute to the work of the late Dr. Angus Smith, for he stated that Dr. Koch's invention was first made known and practised in England in 1882 by Dr. Angus Smith.

On the other hand, Dr. Percy Frankland has put forward a claim, in his work on "Micro-organisms in Water" (page 119), that Koch's method was introduced into this country by himself—a claim reiterated in his evidence before the Royal Commission on Metropolitan Water Supply at Question 11099 (Prof. Dewar). "I believe you tell us that you were the first person in this country who adopted the Koch method, and applied it to the London Water Supply?" "Yes, that is so."

As I was scientific assistant to the late Dr. Angus Smith, and worked with him on Dr. Koch's gelatine method, I should like to state that not only was the method applied by Dr. Angus Smith to the London Water Supply in February 1883, but also to a variety of waters from different parts of the country. The results of Dr. Angus Smith's work are to be found in the second Report of the Local Government Board R.P.P. Act, 1876.

Ellerslie, Alderley Edge, May 6. FRANK SCUDDER.

I AM much indebted to Mr. Scudder for furnishing an opportunity for calling attention to a misapprehension which appears to exist in some quarters as to the time and manner in which Dr. Koch's method of water examination by the process of gelatine-plate-culture was introduced into this country, as but for his letter I should not have thought it worth while to discuss a matter which must be sufficiently well known to all who are really conversant with the development of bacteriological inquiry in Great Britain during the past fifteen years. In the first place, I would point out that in making the statements referred to by Mr. Scudder, I did so with the full cognisance of the late Dr. Angus Smith's work as published by him in his second Report to the Local Government Board, and in an article of his which appeared in the *Sanitary Record* in 1883. In this work I was so much interested that I at once, in the same year, set about applying the method described by Dr. Angus Smith to a number of the samples of London and other waters which were being subjected to analysis in my private house at the time. These experiments yielded, however, such indefinite and unintelligible results that I entirely abandoned Dr. Smith's process, and it was not until the summer of the following year (1884) that I became really acquainted with Koch's method of plate-cultivating bacteria through the now classical demonstrations given by Mr. Watson Cheyne at the Health Exhibition. It was this method of gelatine-plate-culture which I then immediately applied to the investigation of a number of problems connected with the bacterial purification of water by filtration, precipitation, &c., both on the laboratory and on the industrial scale, and the results of which I placed in the hands of the Royal Society in May 1885, in a paper entitled "The Removal of Micro-organisms from Water." It is this paper which I believe to be the first published account in this country of the application of what is now universally understood as "Koch's gelatine-plate-process" to the examination of water, and the first to contain numerical determinations of the bacteria present in a given volume of the various waters supplied to London. In the autumn of the same year (1885) I undertook, at the request of the late Sir Francis Bolton, then Water Examiner for the Metropolis, to make for the Local Government Board regular monthly examinations by this process of the various waters, both before and after filtration, supplied by the several London Water Companies, and the results of these were regularly published in the monthly reports issued by the Local Government Board.

That I do not stand alone in viewing Dr. Angus Smith's method and that of Dr. Koch as distinct, will be apparent from the following words, extracted from Dr. Smith's above-mentioned Report to the Local Government Board:—"I do not know, even now, if I employ the method which Dr. Koch would consider the best, but the book on the subject promised by himself and his coadjutor not having appeared, I consider myself liberty to proceed with my inquiries"; and in point of fact, if any competent bacteriologist will take the trouble to read Dr. Angus Smith's report, he will see that although both processes of course involve the use of gelatine, they are in many important respects widely divergent. In the first place, the medium employed by Dr. Angus Smith contained gelatine only, and was destitute of the nutrient constituents—meat-broth and peptone; so that the appearance of colonies in his process would thus partly depend upon the chemical composition of the water, a condition of things which tends to defeat the object in view, viz. the discovery of the living as distinguished from the dead and unorganised matter in the water. Indeed Dr. Angus Smith distinctly deprecates rendering the medium more nutritive, *e.g.* by the addition of sodium phosphate and sugar, which he employed in some of his experiments. On the other hand, one of the cardinal principles of Koch's method is the use of as highly nutrient a medium as possible, so as to render the cultivation results absolutely independent of the chemical composition of the water. Again, of fundamental importance in the Koch method is the cultivation in such a thin stratum of the solid medium that all parts of it shall be practically under identical conditions and plentifully supplied with oxygen. Dr. Angus Smith, on the other hand, cultivated in test-tubes eight inches in depth, and the disadvantage of this he appears to have himself realised, as he points out that the cultures of very impure waters suffer from want of oxygen in the depth, and thus lead to erroneous results. In fact I have failed to find in Dr. Angus Smith's publications any mention whatsoever of cultivation on plates or their equivalents in any shape or form, which I hold to be the essence of the process which bears the name of Koch, and to which modern bacteriology is so profoundly indebted. Without, therefore, in any way wishing to detract from the interest attaching to Dr. Angus Smith's independent investigations on the application of gelatine to water examination, it appears to me that as he seems not to have been acquainted with what is known and described in text-books as Koch's method of water examination, he cannot obviously be said to have introduced it into this country. Indeed, I cannot personally find any more justification for the statement that Dr. Angus Smith practised Koch's method of gelatine-plate-culture in 1882, than there would be for saying that Hero drove a steam locomotive in Alexandria more than a century before the Christian era.

PERCY F. FRANKLAND.

Mason College, Birmingham, May 12.

On the Action of Röntgen Rays and Ultra-violet Light on Electric Sparks.

IN NATURE of April 30, the writer of "Recent Work with Röntgen Rays" has not exactly described the results of our experiments, published in the *Rendiconti dell' Accademia dei Lincei.*

We had formerly found that the sparking distance between two electrodes, in a shunt-circuit on the discharge of an induction coil, which illuminates a Crookes' tube, is strongly diminished if the Röntgen rays sent from the tube fall upon the positive electrode. The phenomenon is very interesting, as it is the reverse of the phenomenon discovered by Hertz, in which the ultra-violet light acts on the sparking distance in lengthening it, when falling on the negative pole.

On subsequent experiments, we found that when the sparking distance was the same as that used with Röntgen rays, the ultra-violet light acted exactly in the same way, and the passive pole —so to say—was then the positive one.

So far we had succeeded in reversing the phenomenon discovered by Hertz, and further investigated by Wiedemann, Ebert, Elster and Geitel, and had shown the parallelism of the two radiations as to their impeditive action on the spark.

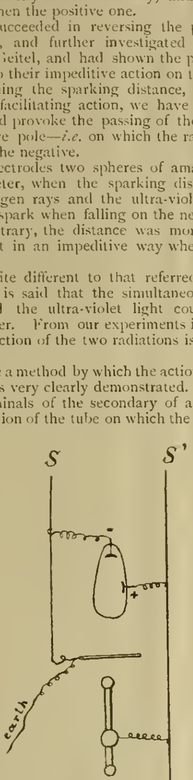
But on diminishing the sparking distance, when the ultra-violet light has a facilitating action, we have shown that the Röntgen rays would provoke the passing of the spark. In the last case the passive pole—*i.e.* on which the radiation must fall —is in both cases the negative.

So taking as electrodes two spheres of amalgamated brass, 52 mm. in diameter, when the sparking distance was below 30 mm., the Röntgen rays and the ultra-violet light provoke the passing of the spark when falling on the negative electrode. When, on the contrary, the distance was more than 30 mm., both radiations act in an impeditive way when falling on the positive pole.

This result is quite different to that referred to in the cited article, in which it is said that the simultaneous actions of the Röntgen rays and the ultra-violet light could be made to neutralise each other. From our experiments it follows, on the contrary, that the action of the two radiations is in every respect identical.

We will describe a method by which the action of the Röntgen rays on the spark is very clearly demonstrated.

S, S' are the terminals of the secondary of an induction coil. In front of the portion of the tube on which the kathode rays fall



s a thin aluminium plate 20 cm. square, in connection with the negative electrode of the Crookes' tube: whilst the positive is connected with a sphere so that the sparks between the plate and the sphere take place in the direction of propagation of the Röntgen rays, to which the aluminium plate is transparent. The plate is connected to the earth. With this apparatus the length of the spark can be made *four* times greater when the Röntgen rays are screened before falling on the aluminium plate. On diminishing the intensity of the current in the primary so as to conveniently shorten the sparking distance, the inverse phenomenon can be obtained, so that the spark does not pass when the Rontgen rays are screened.

Our present researches aim at the study of the alteration of the nature of the discharge when the spark is under the action of the Röntgen rays.

A. SELLA.
Q. MAJORANA.

Istituto fisico della Università di Roma, May 3.

Röntgen Ray Phenomena.

AT one of my demonstrations last week two tubes failed to act. They were both of the kind which depend for their action on a piece of platinum placed within, and from which after bombardment by kathode rays the Röntgen rays take origin. A glance at the tubes showed that owing to the unusual strength of spark the platinums within them were red-hot at the point of impact. Before the demonstration the tubes had been in good working order. I considered they had broken down, but, on returning home, tried them with the spark from my own apparatus, with which they had before answered well. I was somewhat astonished to find them giving off Röntgen rays rather more freely than when first tried. This tends to show that Röntgen rays are not given off by platinum heated above a certain temperature. I think this has already been suggested, but I have not seen it corroborated.

Following up the idea of reinforcing the effect of the Röntgen rays by placing a fluorescent screen under a sensitive film on celluloid, the celluloid side being next the screen to prevent "grain," and having tried screens of barium platino-cyanide, potassium platino-cyanide, calcium tungstate, natural scheelite, artificial scheelite (Edison's), fluor-spar and calcium fluoride, I find that potassium platino-cyanide and artificial scheelite alone produce any effect through celluloid. Barium platino-cyanide, placed underneath, gave no effect either in contact with the sensitive film itself or through celluloid, but the films were not sensitive to yellow, and this salt gives yellow fluorescence. The effect with potassium platino-cyanide was decidedly the best.

Chard, May 3. J. WILLIAM GIFFORD.

Alpenglühen.

AFTER the shadows of the lower mountains have swept up past the tops of the higher snow peaks, *i.e.* after the sun has set upon these last, and as the general light of the sky fades, the contrast between the illumination of the snow and of the sky usually increases. The westerly-facing snow peaks stand out against the darkened sky, and gradually change in tint. Very often the most noticeable change is to a clear greenish-white. But sometimes there is a period during which they have a faint rose or crimson glow. This is the true Alpenglühen; often confused by tourists with the ordinary rose-coloured illumination preceding the setting of the sun.

I see (NATURE, vol. liii. p. 588) that it has been suggested that this afterglow is due to what practically amounts to a second rising of the sun upon the high snow, owing to a peculiar arrangement of layers of hot and cold air in the atmosphere. This may be so; but it is rather a startling theory, and should be tested by observations from, say, the higher or lower observatories of Mont Blanc, simultaneously with observations of the Alpenglühen made from below anywhere to the west. A reappearance of the sun would be an interesting sight for the higher observer. In the meantime, my own observations of some twelve or thirteen summers would lead me to suggest the following explanation. In the first place, I do not think that the afterglow is nearly as vivid as an observer believes. To the eye, the stars "come out," and the moon becomes almost dazzling, as the general light of the sky fades; and both "fade" as day breaks.

Next, I noticed the following during five months of uninterrupted observations of sunsets in the plains of Argentina. On some fine evenings, there was left, as daylight faded, a vivid line or band (of uneven thickness) of intense crimson colour in the west. This was so strong and so well defined that it lit up the westerly face of the estancia with crimson, and actually threw a fairly sharp shadow of the horizontal gutter. Vertical poles, &c., had of course no shadow; the source was too long in a horizontal direction. This crimson streak did not appear always, by any means. The westerly sky itself often passed through various tints of a clear greenish-blue.

It seems to me that, considering the snow heights facing the

west, what has been pointed out concerning the fading of the rest of the sky, the comparative localisation of light and colour in the west, and the illusion as to brightness that occurs when the background fades, the phenomenon of Alpenglühen, and that of the greenish illumination so often seen, can be accounted for without the help of the startling hypothesis quoted.

But it would be more satisfactory if observations could be made from above. Would M. Vallot sacrifice himself and spend some nights up in the observatories that he directs?

R.N.E. College, Devonport. W. LARDEN.

The Positions of Retinal Images.

THE thanks of your psychological readers are due to Mrs. Ladd Franklin for having, in her letter published in your number of February 13, called attention to Schön's experiments, which, as she says, have been unaccountably overlooked. I have in consequence been repeating the experiment which Mrs. Franklin describes, but so far with purely negative results. Although some of the observers gave answers which might hastily have been interpreted as confirmations of Schön's illusion, a further analysis showed conclusively that no one on whom I have experimented, so far, perceived it.

Allow me to indicate one or two points in Mrs. Franklin's letter which seem to require elucidation. She writes as if the object looked at in the experiment "consists of a single bright point." But surely the point H in her diagram—the fixation point—was a bright point as well as O or O'? In Schön's experiments the apparent distance of O or O' was judged relatively to H (which was a stick of phosphorus), by the "stereoscopic (or pseudoscopic) effect," and his explanation of the illusion was that we (unconsciously) judge as if the image actually produced on the right retina had been produced on the left, and *vice versa*. The image on each retina consists of two bright points, but cannot strictly be called a "double image," since the bright points are produced by two distinct objects—by the phosphorus at H, and by the light proceeding from O' or O. If Schön's explanation is correct, then, supposing the light really proceeds from O', and when the ray O' r' is darkened appears to come from O, the observer ought to say the object appeared to be not merely as far off as H, but a *long way* behind it. Further, if the ray O' l' is darkened instead of O' r' there ought to be no illusion—he should say the object appears much nearer than H (*i.e.* still at O'); and if either ray is cut off altogether, he will have no reason for judging the object to be at O', but will probably judge it to be further back—where the source of light actually is. In my experiments, so far, none of the observers have made any distinction between cases where the ray O' r' was darkened and those where the ray O' l' was; but if either of them was darkened considerably, they answered just as they did when one of them was totally extinguished; judging the object to be about where the source of light actually was—which was about the same distance as the phosphorus mark H, and very much nearer than the point O would have been.

I hope to continue the experiments, if possible until I get a positive result, and should be glad therefore to hear some further details of Mrs. Franklin's experiments, especially with reference to the points I have brought forward, either privately or through your columns. EDWARD T. DIXON.

4 Cranmer Road, Cambridge, April 17.

Colour Variations in Ducks and Pigeons.

ABOUT a year ago you published a short article by Mr. Francis Galton (April 11, 1895, vol. li. p. 570), in which he urged the desirability of making careful records of all cases of "sports" (sudden variations in domesticated animals, &c. Two such sports having arisen recently under my own observation, one in ducks and one in pigeons, I write to place the facts before your readers.

(1) *Ducks.*—In January 1894, I bought in Beyrout market a drake of the common "Mallard" colours and four ducks, two of normal wild-duck colour, one pure white, and one black, splashed with white. From these ducks I raised, the same season, thirty-six ducklings; and, from eggs given by a friend, nine more. Concerning the latter, nothing need be said at present, except that their own mother was of a very dark, dingy brown, and the ducklings were nearly black in the down. Of the thirty-six ducklings hatched from my own ducks' eggs, twelve or thirteen (I neglected to note the exact number at the time) were different in colour from their olive-green brethren and from anything I had seen before, being of a beautiful pale fawn colour above, shading into canary-yellow beneath, with darker pencillings and shadings on the sides of the head and back, and with the normal, symmetrical series of three pairs of light marks on the upper surface, distributed just as in normal, olive-green ducklings. The entire set of these pale ducklings proved to be females, and their plumage, when adult, was a pretty yellowish or sandy buff colour, with darker shadings, due to a brown streak down the middle of each of the contour-feathers. The speculum on the wing gave mostly sky-blue reflections, instead of the usual metallic green of common ducks. Two only of the dozen (or thirteen) differed perceptibly from the others, being of *uniform* cinnamon-brown colour, with white throats.

Five of these pale ducks were kept and allowed to breed, viz. one cinnamon-brown and four yellow ones. In addition, my stock during the season of 1895 consisted of three of the original old ducks (one white, one black, and one normal); three normal-coloured young ducks related to the pale ones (*i.e.* same paternity, and presumably same maternity to some extent); and two ducks raised from the eggs given by my friend, as above mentioned, and therefore non-related to the others—in all thirteen ducks. Of drakes there were four—two of normal mallard colour (related, as above, to the pale ducks), and two own brothers to the dark ducks, these having green heads and beautifully-pencilled stone-grey bodies, with no brown on the breast and no white collar—a departure from typical drake-colouration which is normal (in Syria at least) to dark varieties.

From this stock of ducks I raised last spring sixty-two ducklings, of which nineteen were fawn-coloured in the down. One of these died very young. Of the remainder, fourteen were females and four males. All were sandy-buff, none cinnamon-brown; but one—a female—was a shade or two darker than the rest, and when adult showed no metallic colours on the speculum, agreeing in this respect with the dark ducks of alien parentage.

Of greatest interest to me was the question: What will the "yellow" drakes be like when adult? Time has answered as follows: Head and neck, soft *coffee brown*, with obscure greenish reflections in some lights; narrow white collar; chestnut-brown breast, similar to mallard; upper tail-coverts (including curled feathers), and under-tail coverts, chocolate-brown; the rest delicate cream colour, with fine transverse pencillings on back and sides, similar to those on the mallard, but paler and less distinct: the whole effect very pleasing.

Of course all this may be familiar enough to some people, but it is quite new to me, and no mention of such drakes is made by Darwin in "Animals and Plants," nor by any other writer whose works I have been able to consult. Whether atavism has anything to do with the matter, I cannot say, as the parentage of my original stock is entirely unknown; but I am accustomed to notice very carefully all the ducks I see about town and the surrounding country, and am sure I have never come across any such during an experience of about twenty-five years. In any case, it is interesting to note that the new variety was far from being "swamped" by the inevitable crossing with its parent form.

(2) *Pigeons.*—In 1894 I procured a pair of birds of a variety known to Arab fanciers as black *Urjani* (or *Shamandarûzi*). These are largish pigeons, wholly black, with two "red" (*i.e.* bright reddish brown) bars on each wing, corresponding to the black bars on normal "blue" pigeons. The pair were unrelated, the male coming from Hums, the female from Damascus. The variety is scarce in Beyrout, and is valued more or less by all Syrian fanciers, who breed it with some care; and it habitually breeds true. My birds produced during the season of 1895 ten young ones: six (3 ♂, 3 ♀) quite normal in colour; one (♀) slightly mottled on the shoulders with brown and a very little white; and three (all ♀), which in the nest plumage were uniform *light red*. (I had not a red bird in the loft—scarcely a red feather, aside from the red bars of the *Urjanis* themselves, so there was no question of illegitimate paternity.) But, strange to relate, when these red birds moulted, nine-tenths or more of their red feathers were replaced by *pure white*, so that their adult plumage may be described thus: *white* birds with red neck, abdomen red mottled with white, a very few red feathers scattered over back and shoulders; no trace of red bars.

Careful inquiry among Arab fanciers having personal experience of the breed in question, elicited the following

information. Black *Urjanis* usually breed true; when they fail to do so, the progeny is generally a sport of a particular kind called *dijji*, uniformly red when young, more or less mottled with white when adult. These *dijjis* are apt to "throw back," and in turn produce good *Urjanis*.

One of my own mottled birds (*dijji*) remains in my possession, and is now mated to an *Urjani*—an own brother. The pair has produced this spring four young: three *dijjis*, just like the mother, and one partial reversion to the *Urjani* form, being dark-chequered blue, with red bars on the wings. The original parent pair of *Urjanis* have also raised four squabs this season—three normal and one *dijji*; sexes not yet determined. I state these facts without comment; but would be glad to know whether fanciers in England or elsewhere have observed anything quite as striking in the way of colour-variation.

W. T. VAN DYCK.

Beyrout, Syria.

Dependence of the Colour of Solutions on the Nature of the Solvent.

IT is a well-known fact that the colour exhibited by one and the same body in solution depends more or less on the nature of the solvent. In some cases this phenomenon can be satisfactorily accounted for by electrolytic dissociation, but in the majority of cases hitherto examined this explanation is not admissible. Perhaps the most striking of these is that of iodine, the solutions of which are coloured variously violet, blue, brown, and yellow. The hypothesis has been put forward that the variation in absorption might be due to the formation of molecular aggregates of variable complexity; but this, at least in the case of iodine, has been rendered very improbable by the recent researches of Beckmann and others. Nor does the hypothesis that the variation may be due to a varying degree of combination with the solvent seem much more promising.

If, now, absorption be a case of electrical resonance, should one not expect a relation between the absorption of the dissolved body and the physical properties of the solvent, sufficient to account for the observed variations? That such a relation should exist, seems possible from the following rough considerations.

The period of vibration of an electric oscillator is, in the usual notation,

$$T = 2\pi\sqrt{LC},$$

where L = self-induction, and C = capacity. But now:—

$$LC = gK\mu,$$

where g is a geometrical factor and K and μ are the dielectric constant and permeability of the surrounding medium. Also $n^2 = K\mu$, where n is the index of refraction of the medium for very long waves, whence it follows that

$$T = 2\pi n\sqrt{g},$$

which means that the principal absorption-band should travel towards the red end of the spectrum as the index of refraction of the solvent increases. This result is identical with the general qualitative law enunciated many years ago by Kundt, on the basis of experimental data. There are, it is true, various breaks in the parallelism; still this mode of viewing the question seems to offer more possibilities than the others.

F. G. DONNAN.

Hatching Lizards' Eggs.

CAN any of your readers suggest a way to hatch lizards' eggs? I have had a pair of bright-green lizards (I think they came from Italy) in a glass vivarium in a very sunny window for two years and a half. Last year, on May 19, the female laid eleven eggs. I left them exactly as the mother laid them, and after about three weeks I opened one and found the rudiments of a young lizard; but the other eggs never came to anything. I should like to rear them this year if it is possible.

H. A. ROSS.

Trevean, Penzance.

THE DIFFUSION OF METALS.

IT is now quite usual to think of alloys as being solid solutions and to recognise that the atoms of solid metals are in active movement. That this must be the case, is revealed by the passage of metals to allotropic modifications in which the physical properties differ widely from those of the same metals in their normal state. It is well, therefore, that we should remember how much was done for us thirty years ago by Matthiessen in framing such views, and by Graham in showing that solid metals are true solvents for gases which move and diffuse freely in them, sometimes to reappear with gaseous elasticity.

The experimental portion of the latter work, Graham entrusted to me, and my hope that I should be able to extend his work on the diffusion of salts, to liquid and solid metals, has been somewhat tardily realised by the delivery in the present year of the "Bakerian Lecture" of the Royal Society, of which the following is a brief abstract.

PART I.—*Diffusion of Molten Metals.*

In the first part of it allusion is made to some earlier experiments of my own conducted in 1883 on the diffusion of gold, silver, and platinum in molten lead. It is strange that although the action of osmotic pressure in lowering the freezing point of metals has been carefully examined, very little attention has been devoted to the measurement, or even to the consideration, of the molecular movements which enable two or more metals to form a truly homogeneous fluid mass. The absence of direct experiments on the diffusion of molten metals is probably explained by the want of a sufficiently accurate method. Ostwald has stated, moreover, with reference to the diffusion of salts, that "to make accurate experiments in diffusion is one of the most difficult problems in practical physics," and the difficulties are obviously increased when molten metals diffusing into each other take the place of salts diffusing into water.

The continuation of the research was mainly due to the interest Lord Kelvin had always taken in the experiments. The want of a ready method for the measurement of comparatively high temperatures, which led to the abandonment of the earlier work, was overcome when the recording pyrometer was devised, and the use of thermo-junctions in connection with this instrument rendered it possible to measure and record the temperature at which diffusion occurred. Thermo-junctions were placed in three or more positions in either a bath of fluid metal or an oven carefully kept hotter at the top than at the bottom. In the bath or oven, tubes filled with lead were placed, and in this lead, gold, or a rich alloy of gold, or of the metal under examination, was allowed to diffuse upwards against gravity. The amount of metal diffusing in a given time was ascertained by allowing the lead in the tubes to solidify; the solid metal was then cut into sections, and the amount of metal in the respective sections determined by analysis.

The movement in linear diffusion is expressed, in accordance with Fick's law, by the differential equation

$$\frac{dv}{dt} = k\frac{d^2v}{dx^2}$$

In this equation x represents distance in the direction in which diffusion takes place, v is the degree of concentration of the diffusing metal, and t is the time; k is the diffusion constant, that is, the number which expresses the quantity of the metal in grams diffusing through unit area (1 sq. cm.) in unit time (one day) when unit difference of concentration (in grams per c.c.) is maintained between the two sides of a layer 1 cm. thick. The experiments described in the Bakerian Lecture showed that metals diffuse in one another just as salts do in water, and the results were ultimately calculated by the aid of tables prepared by Stefan for the calculation of Graham's experiments on the diffusion of salts, special tables being calculated by one of my students, Mr. A. Stansfield, in connection with this research.

The necessary precautions to be observed and the corrections to be made were described at length and the

values for k—the diffusivity of certain metals in lead, tin, bismuth and mercury, given in sq. cm. per day, are as follows:—

		k
Gold in lead	... ...	3·19 at 550°
,, bismuth	... ...	4·52 ,,
,, tin...	... ...	4·65 ,,
Silver in tin	... ...	4·14 ,,
Lead in tin	... ...	3·18 ,,
Rhodium in lead	... ...	3·04 ,,
Platinum in lead	... ...	1·69 at 490°
Gold in lead	... ...	3·03 ,,
Gold in mercury	... ...	0·72 at 11°

In order to afford a term of comparison, it may be stated that the diffusivity of chloride of sodium in water at 18° is 1·04.

It is at present too soon to draw any conclusion as to the evidence which the results afford respecting the molecular constitution of metals, but it is evident that they will be of value in this connection, because, with the exception of the gases, they present the simplest possible case which can occur—the diffusion of one element into another. Thus the relatively slow rate of diffusion of platinum as compared with gold, points to its having a more complex molecule than the latter.

It is very difficult within the limits of this brief abstract to show that molten metals actually pass into each other by diffusion. The following method will, however, serve to give a rough qualitative demonstration that such is the case. A white sheet of card, B, is, as Fig. 1 shows, mounted on a frame, and by means of the gearing C C′ can be raised or lowered at a definite rate, which can be maintained by the aid of a metronome. The diffusion cell is shown at A. It consists of a clay tube about 30 mm. long, heated from its upper part so that the top portion of the tube is hotter than the lower portion. This tube is filled with molten lead, and at the bottom of the lead, is a layer of a lead-gold alloy rich in gold. A sample of lead may be withdrawn from the tube at the beginning of a lecture and

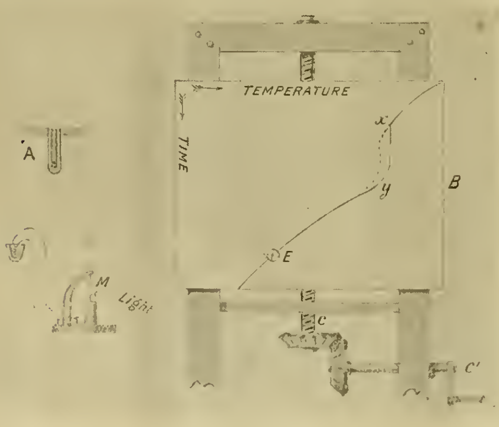

FIG. 1

set aside, while a second sample of lead may be removed at the end of an hour, by which time gold will have diffused into the upper layers of lead, and consequently this second sample will be auriferous. Other experiments have shown that in this case convection currents do not complicate the result.

The proof that gold had diffused into lead can then be afforded by the fact that the point of solidification of the second portion of lead is, owing to the presence of gold in it, lower than that of the first portion, and this is shown to be the case in the following way. The first sample of lead is placed in a small crucible, D, and a

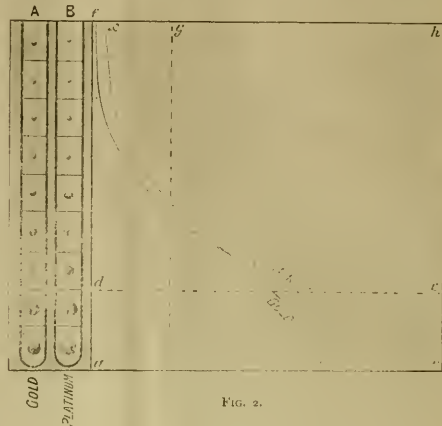

FIG. 2.

protected thermo-junction is immersed in the lead when it is fluid. The spot of light E from the mirror M, of the galvanometer connected with the thermo-junction is allowed to fall on the movable screen, and as the lead cools down the spot of light traverses the screen from right to left. The consecutive positions occupied by the centre of this spot of light are marked by hand with a stroke of charcoal. During the solidification of the metal the spot of light remains in one position, and consequently the portion of the curve which represents the solidification of the metal is the vertical line x, y. If the second sample of lead be treated in exactly the same way, and its "cooling curve" traced, it will be seen that the freezing point is lowered, and a demonstration is thus afforded that diffusion of gold has occurred in the lead contained in the tube A.

The results of the diffusion of platinum and gold in fluid lead during twenty-four hours is shown diagrammatically in Fig. 2. The lead was placed in tubes which were arranged side by side in the oven, to which reference has been made. The columns A B represent the actual length and diameter of the columns of fluid lead. The spheres, which are drawn to the left of the diagram, are slightly smaller than the buttons of gold and of platinum extracted from the several sections, shown by horizontal lines, into which the columns of lead were divided after the metal had been allowed to solidify. The curves represent the respective diffusivity of gold and of platinum. The vertical ordinate represents the *distance* in the direction in which diffusion takes place, and the horizontal ordinates *concentration* of the diffusing metal. Each of the metals gold and platinum which diffused into the fluid column of lead occupied in the form of an alloy rich in lead, the length a d, of the

tube, and in both cases, the initial concentration of the alloy, denoted by *a c*, from which diffusion proceeded, was the same, so that the area, *a c e d*, represents the total amount of gold or platinum employed in the experiment, the whole quantity of either metal being initially below the line *d e*. The final state of complete diffusion would be represented by the area *a b g f*, which is the same as *a c e d*, since the quantity of gold or of platinum remains unaltered. In the same manner the area *a y x f*, would represent the distributions of the gold at the end of the experiment, and consequently in experiments which have lasted for equal times, the nearer the curve approximates to the line *b*, *g*, the more rapid is the diffusion of the metal it represents. It will be evident from the distribution of the spheres of gold and platinum that diffusion can be accurately measured in molten metals.

PART II.—*Diffusion of Solid Metals.*

The second part of the investigation was devoted to the consideration of the diffusion of solid metals. Much of the evidence is historical, for there has long been a prevalent belief that diffusion can take place in solids, and the practice in conducting important industrial operations supports this view. In this connection two truly venerable "cementation" processes may be cited. The object in the first of these is the removal of silver from a solid gold-silver alloy, while the second is employed in steel making by the carburization of solid iron. In both of these processes, however, a gas may intervene, though the carburization of iron by the diamond, which, in 1889, I effected *in vacuo*, suggests that if a gas does intervene in the latter case, its quantity must be very minute. In connection with the mobility of various elements in iron the work of Colson, of Osmond, and of Moissan must be carefully kept in view.

The electro-deposition of metals also affords evidence of the interpenetration of metals. I observed in 1887 that an electro-deposit of iron on a clean copper plate will adhere so firmly to it that when the metals are severed by force, a copper film is actually stripped from the copper plate and remains on the iron, thus affording clear evidence of the interpenetration of metals at the ordinary temperature, and this interpenetration of copper and iron will take place through an intervening film of nickel.

My friend Dr. George Gore has given me the following interesting reference to the penetration of gold and platinum at a temperature below redness, which is recorded in "Weldon's Register" for July 1863 by Edward Sonstadt, who states that he gilded a platinum crucible "inside and out . . . but no sooner was the platinum warmed than it began to change colour, and before the crucible attained visible redness not a vestige of the gilding remained."

This is interesting in connection with the earlier observation of Faraday and Stodart, who in 1820 showed that platinum will alloy with steel at a temperature at which even the steel is not melted, and they expressed their interest in the formation of alloys by cementation, that is by the union of solid metals.

The remarkable view expressed by Graham, in 1863, that the "three conditions of matter (liquid, solid, and gaseous) probably always exist in every liquid or solid substance, but that one predominates over the other," affords ground for the anticipation that metals will diffuse into each other at temperatures far below their melting points. The important work by Spring, in 1886, on the lead-tin alloys, showed that they retain a certain amount of molecular activity after they become solid, and special importance will always be connected with the proof afforded by him (1882), that alloys may be formed either by the strong compression of the finely divided constituent metals at the ordinary temperature, or (1894) by the union of solid masses of metal compressed together at temperatures which varied from 180° in the case of lead and tin, to 400° in the case of copper and zinc; tin melting at 227° and zinc at 415°.

Early evidence as to the volatilisation of solid metals may be traced to the expression of Robert Boyle's belief, that even such solid bodies as glass and gold might respectively "have their little atmospheres, and might in time lose their weight," and Merget's experiment on the evaporation of frozen mercury is specially interesting in relation to Gay-Lussac's well-known discovery that the vapours emitted by ice and water both at 0° C., are of exactly equal tension. Demarçay's experiment on the volatilisation of metals *in vacuo* at comparatively low temperatures is, moreover, connected with the evidence afforded by Spring (1894), that the interpenetration of two metals at a temperature below the melting point of the more fusible of the two is preceded by volatilisation.

It is well to remember, however, that interesting as the results of the earlier experiments are, as affording evidence of molecular interpenetration, they do not, for the purpose of measuring diffusivity, come within the prevailing conditions in the ordinary diffusion of liquids, in which the diffusing substance is usually in the presence of a large excess of the solvent, a condition which was fully maintained in the experiments on the diffusion of liquid metals described in the first part of the Bakerian Lecture. Van 't Hoff has made it highly probable that the osmotic pressure of substances existing in a *solid solution* is analogous to that in liquid solutions, and obeys the same laws; and it is probable that the behaviour of a solid mixture, like that of a liquid mixture, would be greatly simplified if the solid solution were very dilute.

The experiments on the diffusion of solid metals are of the same nature as in the case of fluid metals, except that the gold, which was the metal chosen for examination, was placed at the bottom of a solid cylinder of lead instead of a fluid one.

In the first series of experiments, cylinders of lead, 70 mm. long, with either gold, or a rich alloy of gold and lead at their base, were maintained at a temperature of 251° (which is 75° below the melting point of lead) for thirty-one days. At the end of this period the solid lead was cut into sections, and the amount of gold which had diffused into each of them was determined in the usual way. Other experiments were made, in which the lead was maintained at 200°, and at various lower temperatures down to that of the laboratory. The following are the results in sq. cm. per day:—

				k
Diffusivity of gold in	fluid	lead at	550	... 3·19
,,	solid	,,	251	... 0·03
,,	,,	,,	200	... 0·007
,,	,,	,,	165	... 0·004
,,	,,	,,	100	... 0·00002

The experiments at the ordinary temperature are still in progress, but there is evidence that slow diffusion of gold in lead occurs at the ordinary temperature. If clean surfaces of lead and gold are held together *in vacuo* at a temperature of only 40° for four days, they will unite firmly, and can only be separated by the application of a load equal to one-third of the breaking strain of lead itself. The nature of welding, however, remains to be investigated, as there is probably interlocking of molecules and atoms, which precedes true diffusion. It may be considered remarkable that gold placed at the bottom of a cylinder of lead, 70 mm. long (which is to all appearance solid), will diffuse to the top in notable quantities at the end of three days. At 100° the diffusivity of gold in solid lead can readily be measured, though its diffusivity is only 1/100,000 of that in fluid lead at a temperature of 500°, and experiments which are still in progress show that the diffusivity of solid gold in solid silver, or copper, at 800° is of the same order as that of gold in solid lead at 100°.

I trust, therefore, that the experiments described in the Bakerian Lecture will show that the diffusion can readily be measured in solid metals, and that they will carry one step further the work of Graham.

W. C. ROBERTS-AUSTEN.

BOOKS ON BIRDS.[1]

THE issue of works on ornithology continues in an unbroken stream. There can be little doubt that since the arrangement of the birds in the National Museum in South Kensington, in their natural attitudes and surroundings, was adopted—a system largely followed in many of our provincial museums—there has been a distinct increase in the interest taken in natural history, and, as might be expected from the amount of knowledge as to their life and habits which these groups convey, the study of birds has largely increased. The constant demand for work after work on the limited subject of British birds is very remarkable, and is to some extent a measure of the growing interest in this branch of science.

With the second volume, which has lately appeared, Dr. R. Bowdler Sharpe has completed his "Handbook to the Birds of Great Britain" in Allen's Naturalist's Library, of which he is the editor. His knowledge of the subject of which he treats is admittedly unrivalled, while the thorough manner in which he performs all his work—though vast in amount—is so well known, that his name, as editor and author, is sufficient guarantee for the value and excellence of these two volumes. All that is essential to be known in the life-history of British birds is related shortly yet fully, in clear, popular language. This work forms a concise monograph of our native birds; indeed, no better or more authoritative work on the subject has yet been published. It is illustrated by numerous coloured full-page plates, the bulk of them the resuscitated drawings of Lizars from Jardine's Library. As has been often already pointed out, and pressed upon the attention of the publishers in regard to other volumes of this series, those plates are quite unworthy of the text. In the preface to the second volume the author replies to the critics who have attacked his method of nomenclature adopted in this and other volumes of the Library, the result of which is that certain species come to be designated by a duplication of their generic and specific names. Dr. Sharpe appears to us to have adopted the only logical course open to him, and his reply would seem to be unanswerable. "Thus if Linnæus," he says, "called the Partridge *Tetrao perdix*, the name *perdix* ought to be retained at all costs for the species. When *Perdix* was taken in a generic sense and the species was called *Perdix cinerea*, I contend that it ought never to have been allowed, and if in restoring the Linnæan specific name of *perdix*, it results that the oldest generic name is also *Perdix*, and the species has to be called *Perdix perdix* (L.), I can only say I am sorry, but it cannot be helped."

In Mr. Hudson's "British Birds" a brief account is given of the appearance, language and life-habits of all the birds that reside permanently or for a portion of each year within the limits of the British islands. The descriptive accounts of the various species are shorter, less technical and precise, but not less accurate than those in Dr. Sharpe's "Handbook." On the other hand, our author trusts that his work has the merit of simplicity, as it is intended for the general reader and, more especially, for the young. The species alone are described, the family and generic characters being omitted, as there was not space to make the book, "at the same time, a technical and a popular one." Like all that comes from Mr. Hudson's pen on this subject, the present volume is sympathetically and attractively written. It is illustrated by eight chromolithograph plates from original drawings by A. Thorburn, in addition to eight full-page plates and one hundred figures in black-and-white, from drawings by G. E. Lodge, prepared for this work, the whole of which are exquisitely reproduced. Altogether the book is to be very highly recommended. It is prefaced by a chapter on structure and classification by so competent an anatomist as Mr. F. E. Beddard, F.R.S. His contribution, however, though very clear and condensed, is, we fear, somewhat above the heads of the bulk of the young readers for whom Mr. Hudson's pages have been written. On p. 17, he remarks, with reference to the fore-limb in *Dinornis* that no trace of a wing has been so far discovered. In 1892 a scapulo-coracoid, with a distinct glenoid cavity, was figured in NATURE (vol. xlv. p. 257), indicating the presence of a humerus, which is surely at least a "trace" of a wing.

In the "Wild Fowl and Sea-Fowl of Great Britain," a "Son of the Marshes" depicts the haunts rather than the habits of the birds of our estuaries and fen-lands. His volume is more a collection of shooting sketches than a serious contribution to ornithology, notwithstanding the short technical descriptions, at the conclusion of each chapter, of the several species of the group to which the chapter is devoted. The author has given us during many years numerous delightful sketches of marsh-land life at every season, and under all conditions of sky and temperature; but we have had his message so often now, that it has begun to lose much of its freshness and flavour. In this latest delivery we cannot resist the impression that we have heard all he tells us before, and said even better than here. Many of his pages leave with the reader the irritating suspicion of having been elaborated with toil, and the matter beaten out to cover an allotted space. The numerous quotations from all sorts and conditions of marsh-folk, "coy" men, net-setters, and wild-fowlers, in which we fail, through obtuseness probably, to perceive anything humorous, quaint or original, might have been largely curtailed with advantage to the narrative. J. A. Owen, who edits the volume, has allowed to escape detection such unorthodox expressions as "to flight" and "flighting birds," as also the use of that most objectionable term "scientist," to indicate the professed man of science. The volume has numerous excellent full-page black-and-white illustrations by Bryan Hook.

[1] "A Handbook to the Birds of Great Britain." By R. Bowdler Sharpe, LL.D. Vol. i. 1894. Pp. xxii + 342. Vol. ii. 1895. Pp. xi + 308. (London: W. H. Allen and Co., Ltd.).

"British Birds." By W. H. Hudson, C.M.Z.S. With a Chapter on Structure and Classification, by Frank E. Beddard, F.R.S. Pp. xviii + 363. (London and New York: Longmans, Green, and Co., 1895.)

"The Wild-Fowl and Sea-Fowl of Great Britain." By a "Son of the Marshes." Edited by J. A. Owen. With Illustrations by Bryan Hook. Pp. 326. (London: Chapman and Hall, Ltd., 1895.)

"Birds from Moidart and Elsewhere; drawn from Nature." By Mrs. Hugh Blackburn. Pp. viii + 191. (Edinburgh: David Douglas, 1895.)

"The Birds of Berwickshire, with Remarks on their Local Distribution, Migration, and Habits, and also on the Folk-lore Proverbs, Popular Rhymes and Sayings connected with them. By George Muirhead, F.R.S.E. In two volumes. Vol. i. 1889. Pp. xxvi + 334. Vol. ii. 1895. Pp. xii + 390. (Edinburgh: David Douglas.)

"North American Shore Birds: a History of the Snipes, Sandpipers, Plovers, and their Allies." By Daniel Giraud Elliot, F.R.S.E. With seventy-four plates. Pp. viii + 268. (London: Suckling and Galloway. New York: Francis P. Harper, 1895.)

"The Birds of Ontario, being a Concise Account of every Species of Bird known to have been found in Ontario, with a description of their Nests and Eggs, and Instructions for Collecting Birds and Preparing and Preserving Skins, and Directions how to form a Collection of Eggs." By Thomas McIlwraith. 2nd edition. Pp. ix + 426. (London: T. Fisher Unwin; Toronto: William Briggs, 1894.)

"Birdcraft; a Field-book of Two Hundred Song, Game, and Water Birds." By Mabel Osgood Wright. With full-page plates. Pp. xvi + 317. (New York and London: Macmillan and Co., 1895.)

"Photographs of the Life-History Groups of Birds in the Grosvenor Museum, Chester." Prepared by Mr. R. Newstead, Curator; photographed by G. W. Webster. 1895.

"The Royal Natural History." Edited by Richard Lydekker, B.A., F.R.S. Vol. iv. Birds (chaps. viii.-xxi.). Pp. xv + 583. (London: Frederick Warne and Co., 1895.)

"The Fauna of British India, including Ceylon and Burma." Published der the authority of the Secretary uf State for India in Council. Edited by W. T. Blanford. Birds. Vol. iii. By W. T. Blanford, F.R.S. p. xiv + 450. (London: Taylor and Francis; Calcutta and Bombay: hacker and Co.; Berlin: Friedländer, 1895.)

We next come to notice two local faunas. The first of which is Mrs. Hugh Blackburn's "Birds from Moidart and Elsewhere." The authoress is a well-known artist, and the volume before us is not so much a systematic avi-fauna of the region in which she resides, as a series of drawings from nature, all of them artistic, vigorous, and true to life, of such birds as she has known personally, "to which are added," as she tells us in the preface, "simply, and I trust truthfully, a few observations which I have had the opportunity of making on their life and habits." Her sketch of the young and callow cuckoo ejecting the rightful meadow pipits from their nest, is the original illustration of this most interesting fact, which, first made known by Henry Jenner in 1788, and long rejected as apocryphal, was in 1871 re-described, and still more fully established in 1872, when it was sketched from actual observation by Mrs. Hugh Blackburn. Her plates illustrating the habits of many species not to be observed everywhere, such as "Solan-geese fishing," "Cormorants feeding their young," "Osprey carrying a fish," are of real scientific interest and value. So also are the sketches of the nestlings of several birds whose breeding-places are chosen in out-of-the-way corners, whither our artist seems to have followed them. Mrs. Blackburn states the interesting facts that in 1856 there were no starlings in Moidart, where they are now plentiful, and not for many years after were there any common sparrows. On the advent of the latter, however, the yellow-hammers, "which used to be very common," began to decrease rapidly. She records also, on the faith of a correspondent, that a nightingale was heard for three weeks, and also seen during the month of June 1889, "at Achnacary," which, if the observation can be depended on, is a far cry beyond its usual northern limit. On turning to Dr. Sharpe's and Mr. Hudson's volumes, noticed above, we find it recorded that in Scotland and Ireland the nightingale is unknown. (!)

"The Birds of Berwickshire," by Mr. George Muirhead, of which the first volume was published in 1889, and the second in 1895, contains a full account of every bird known to occur in that extensive shire. The work, published by David Douglas, of Edinburgh, is printed on special paper, and on its pages space and variety of type have been generously lavished. Each bird's history is concluded by a charming pen-and-ink etching of its nest, of one of its favourite haunts, or of some interesting, historical, or beautiful Berwickshire "bit," which has more or less direct reference to the subject of the chapter. There are, in addition, several full-page etchings by Scottish Academicians, and an excellent map of the county. Altogether, therefore, no expense has been spared (as is wont with the publishing house of David Douglas) to produce a work worthy of its predecessors in their sumptuous Natural History Library. And although these volumes can but record few new facts about the birds described in them except what is of local distributional interest, they are full of folk-lore, proverbs, popular rhymes and sayings about them, which must ensure the book being greedily desired as a prized addition to his volumes *de luxe*, not only by every lover of birds and their haunts, but by all who treasure dainty books.

The three volumes next on our list follow much the same lines as those above noticed, only they deal with American instead of British birds. "North American Shore Birds," by D. G. Elliott, who is well known by his numerous magnificent scientific monographs, "is a popular work and in no sense a scientific treatise," as the preface informs us. Its object is to enable the sportsman and those who love to study birds in their haunts, to know and recognise those they shoot or observe on the wing. "The accounts of their habits have been written, to the best of the author's ability, in language 'understanded of the people.'" Mr. Elliott will, we have no doubt, be fully successful in his object, for his book cannot fail to satisfy both those classes; and we are confident it will be their frequent companion, both "in the open" and in the study. The volume is not a mere compilation, for the record of the habits of most of the species are derived from the author's own experience in the many hunting excursions he has undertaken from arctic Alaska all over the North-American continent, and as far south as Rio de Janeiro. Nearly every species described in the book is illustrated by a full-page plate in black-and-white from drawings of great beauty by Edwin Sheppard, of the Academy of Sciences of Philadelphia, "an artist possessing exceptional talent for portraying birds and bird-life."

Mr. McIlwraith, in his "Birds of Ontario," enumerates 317 species, which he believes to be the complete tale of the birds occurring in the province of his domicile. A short, but sufficient, account is given of their plumage, their range, their distribution in Ontario, and, as they are nearly all migatory, of where they spend the breeding season, as well as of their nests and eggs. In the introduction full instructions are provided for the young collector how to obtain and preserve his specimens.

In "Birdcraft," Mabel Osgood Wright describes and illustrates two hundred song, game, and water birds of North America. Her book is written for the young, in whom she wishes to encourage the study of "the living bird in his love songs, his house-building instincts, and his migrations," to discourage in them the "greed of possession" of the skin, nest and eggs of her feathered friends, and to enable them to identify and properly name the species they may observe in their excursions. To her disciples—may they be many!—she gives this excellent advice: "Take with you three things, a keen eye, a quick ear, and loving patience"; but leave to "the practised hand of science," "the gun that silences the bird-voice, and the looting of nests." The authoress, who is herself, apparently, a keen and sympathetic observer of nature, believes that all the lover of birds wishes to know of their forms closer at hand, on his return from the field, should be sought for, and will be found, in those "great picture-books"—the museums. "Birdcraft" should form an excellent guide to the young American field-naturalist. Unfortunately the chromo-lithograph plates, on which eight to ten species, varying greatly in colour and size, are crowded, leave much to be desired. A "key to the birds" is provided at the end of the book, by which (*a*) land birds, (*b*) birds of prey, and (*c*) game, shore and water birds may be identified by their predominant colours.

The "Life-History Groups of Birds" in the Grosvenor Museum, Chester, most of which have been mounted by the Curator, Mr. Newstead, have been photographed "in life-like attitudes" with the "natural surroundings proper to the particular specimens," by Mr. G. W. Webster of the same city, and offered to the public in a handsome volume. It is hoped by the authors that these pictures "will appeal to curators and museum authorities, to all lovers of birds and nature, and to artists." To curators of museums they may on occasion afford suggestions; but as they are a class who strongly object to imitate slavishly the methods of even the greatest of their colleagues, they will probably prefer to seek inspiration from the same source as Mr. Newstead. To artists and lovers of birds we have no doubt these platinotypes will afford a great deal of pleasure, and in the case of the former they will be extremely useful as models. The weight of the volume and its high price (necessary from the costliness of its get-up) will, however, we fear, militate against a wide circulation, and certainly against its use for frequent and comfortable reference.

The fourth volume of the "Royal Natural History," edited by R. Lydekker, F.R.S., completes the account of

the birds. The contributors on this occasion are Dr. Bowdler Sharpe, Mr. Ogilvie-Grant, and the editor, whose names are sufficient sponsors that the present volume is in no way behind its predecessors, which every section of the press has been unanimous in praising on account of the scientific excellence of the text, and the beauty of the illustrations. As a "Natural History," presenting a popular and comprehensive survey of the subject, the "Royal" is unsurpassed.

The now well-known two first volumes of the "Birds" in the valuable "Fauna of British India," which the India Office has been so well advised in publishing, were written by Mr. Oates. The present volume has been prepared by the editor of the series, Dr. W. T. Blanford, "who," as he says, "has endeavoured to keep the [continuation of the] work uniform in general plan, and to render the change in authorship as little conspicuous as possible." Everywhere throughout the book, the same care and pains that were manifest in Mr. Oates' two volumes are evident in the third before us. Thanks to Hume—the value or extent of whose unsurpassed gift to the nation has yet hardly begun to be appreciated as it must one day be never before has material for an avi-fauna of India, approaching in its richness been anywhere brought together as that now conserved in the British Museum. The amount of comparison and original investigation demanded, consequently, of the authors in compiling for the first time since this collection has been available, the bird-fauna of our Eastern empire, has been enormously extended, as well as facilitated. Although Mr. Oates, on being prevented from completing the work he commenced, by his recall to official duty in India, handed over to Dr. Blanford, on his departure, the notes he had prepared for its continuation (which have been "of very great service," as the author admits), yet the more arduous part of the work had still to be done. That this task, slow, full of drudgery, and testing all the penetration and discrimination of the ornithologist, has been most conscientiously fulfilled, is evident on every page, and with a result in all respects on which Dr. Blanford is to be congratulated.

It had been intended to complete the "Birds" and (with that section) the Vertebrata of India with the present volume; but as the work progressed, it "became evident that the proposed third volume would be of inconvenient size," and it was, therefore, decided to divide it into the present and a concluding volume, which, it is stated, is now in an advanced state of preparation. The volume under notice includes the *Eurylæmi*, *Pici*, *Zygodactyli*, *Anisodactyli*, *Macrochires*, *Coccyges*, *Psittaci*, *Striges*, and *Accipitres*. The different orders are distinguished chiefly by their anatomical characters. The *Striges* are rightly kept distinct from the *Accipitres*; but the *Pandionidæ* are included within its limits. We should rather have seen them constituted a distinct order, *Pandiones*. It is with satisfaction we note that the publication of the final volume will not be long delayed.

NOTES.

THE long list of birthday honours contains the names of a few men distinguished for their scientific attainments. Prof. Max Müller is to be sworn of the Privy Council. Mr. Clements R. Markham, C.B., F.R.S., the President of the Royal Geographical Society, is promoted to be K.C.B., and Dr. David Gill, F.R.S., Astronomer Royal at the Cape, is made a C.B. Dr. J. G. Fitch, who until lately was Chief Inspector in the Education Department, and Mr. Le Page Renouf, the Egyptologist, have been knighted.

THE Chemical Society's Lothar Meyer Memorial Lecture will be delivered by Prof. P. P. Bedson, at an extra meeting of the Society on Thursday, May 28.

THE Cracow Academy of Sciences has appointed Prof. L. Natanson as its representative at the forthcoming Kelvin celebration at Glasgow.

THE Council of the Sanitary Institute have accepted an invitation from the city and county of Newcastle-upon-Tyne to hold a Sanitary Congress and Health Exhibition in that city in the autumn of this year.

PROF. ANGELO HEILPRIN has been appointed to represent the Academy of Natural Sciences of Philadelphia at the Mining and Geologica Millennial Congress, to be held at Budapest, September 25 and 26, in connection with the celebration of the founding of the kingdom of Hungary. Messrs. Persifor Frazer, Angelo Heilprin, Benjamin Smith Lyman, and Theodore D. Rand have been appointed by the Academy as the Committee on the Hayden Memorial Geological Award for 1896.

ON the occasion of the Hungarian Millennium, the Emperor Francis Joseph has authorised the Budapest University to confer the following honorary degrees:—On Prof. Henry Sidgwick, of Cambridge, the honorary degree of Doctor of Political Economy; on Prof. J. S. Billings, of Philadelphia, and on Sir Joseph Lister the honorary degree of Doctor of Medicine; on Mr. Bryce, M.P., Mr. Herbert Spencer, Lord Kelvin, and Prof. Max Müller, the honorary degree of Doctor of Philosophy.

THE conversazione of the Society of Arts will be held at the South Kensington Museum on Wednesday, June 17.

PROF. E. SUESS, the well-known geologist, and Liberal politician, has just retired from his party in the Austrian Parliament.

THE death is announced of Prof. Germain Sée, the distinguished French pathologist, and member of the Paris Academy of Medicine.

A CONVERSAZIONE of the Society for the Protection of Birds will be held at the Royal Institute of Painters in Water Colours, Piccadilly, to-morrow evening.

WE learn, from the *Journal de Botanique*, that M. L. Diguet has been commissioned by the Minister of Public Instruction for France, and by the Museum of Natural History, with a botanical mission to Lower California, where he will probably make a prolonged stay.

MR. MARK JUDGE, Honorary Secretary to the Sunday Society, sends us the following statement of attendances on Sunday last at the great national museums in London:—South Kensington Museum, 2659; Bethnal Green Museum, 799; Geological Museum, 212; British Museum, 1790; Natural History Museum, 2398; National Gallery, 2106. The total is 9864, which number of visitors may be taken to justify the continuance of the Sunday opening of the museums.

THE Croonian Lectures of the Royal College of Physicians will be delivered on June 2, 4, 9 and 11, by Dr. George Oliver, who will take for his subject "The Study of the Blood and the Circulation."

ON Tuesday next, May 26, Prof. T. G. Bonney, F.R.S., will begin a course of two lectures, at the Royal Institution, on the "Building and Sculpture of Western Europe" (the Tyndall Lectures). On Thursday (May 28) Dr. Robert Munro will deliver the first of two lectures on "Lake Dwellings," and on Saturday (May 30) Dr. E. A. Wallis Budge, Keeper of the Egyptian and Assyrian Antiquities, British Museum, will begin a course of two lectures on the "Moral and Religious Literature of Ancient Egypt." The Friday evening discourse on June 5 will be on "Electrical and Magnetic Research at Low Temperatures," the lecturer being Prof. J. A. Fleming, F.R.S.

A severe storm is reported by Reuter to have swept over Sherman, Texas, on Friday afternoon, completely destroying the western portion of the town. It is estimated that 120 persons, a large proportion of whom were negroes, were killed, and that 100 were injured. The storm, which travelled in a northerly direction over a path of 400 yards wide, swept everything before it. A waterspout burst at the same time over Howe, Texas, where eight persons were killed and many injured.

The Swedish Tourists' Club has organised an expedition to the Great Lake Falls next August. The object of the expedition is to give those who join it an opportunity of seeing the total eclipse of the sun on August 9, of becoming acquainted with Lapland, and at the same time to see two of the finest waterfalls in Europe—the Great Lake Falls (Stora Sjöfallet) and Harsprånget. The party will start from Gellivare on August 3. Further information with reference to the journey can be obtained at the Tourists' Club, No. 28 Fredsgaten, Stockholm.

Prof. S. P. Langley, who has for some time devoted attention to the problem of artificial flight, appears to have attained a remarkable degree of success. The New York correspondent of the *Daily Chronicle* reports that trials made with Prof. Langley's "aërodrome" have clearly demonstrated the efficiency and practicability of the invention. It is stated that "two upward ascents of about half a mile were made at a speed of twenty miles an hour. The machine in motion suggests a huge bird, soaring in large curves. When the steam gave out, the aërodrome sank gracefully and was picked up undamaged. No passengers were carried in the trial trips."

With reference to the reported dispatch of an American Antarctic Expedition under Dr. Cook, which was referred to in Nature last week, we observe in the new number of the quarterly *Bulletin* of the American Geographical Society, New York, that the report is entirely incorrect, and that there does not appear to be "any immediate prospect of the launching of such an enterprise." The Belgian expedition, on the other hand, seems to be in course of rapid organisation; but it does not appear that the necessary funds have yet been completely subscribed. It will be under the command of Lieut. de Gerlache, of the Belgian Navy, and M. Arctowski will have charge of the oceanographical work to be carried out on board.

The second annual meeting of the Botanical Society of America will be held in Buffalo, N.Y., on Friday and Saturday, August 21 and 22, 1896. Dr. William Trelease, Director of the Missouri Botanical Garden, will retire from the presidency, and will be succeeded by the President-elect, Dr. Charles E. Bessey, Professor of Botany in the University of Nebraska. At the evening session on Friday, August 21, the retiring President will deliver a public address on "Botanical Opportunity." The Botanical Society of America is affiliated with the American Association for the Advancement of Science, the sessions of which this year begin on Monday, August 24, in Buffalo.

The Batavian Society of Experimental Philosophy at Rotterdam has offered prizes for the following botanical subjects:—The anatomical and chemical composition and vital functions of one or more at present undescribed species of plant natives of Holland or of the Dutch colonies; description of the vital conditions and properties of a mould-fungus, ferment, or bacterium of technical importance; new investigations on the action of flowers of sulphur or of copper salts on a pathogenous parasite; investigations on the presence, formation, and properties of the latex in the leaves of the caoutchouc-plant. For each subject a medal worth thirty duc. is offered; the work must be hitherto unpublished, and may be written in Dutch, German, French, or English. The essays must be sent, before February 1, 1897, with a motto, and the name in an enclosed envelope, to Dr. G. J. W. Bremer, Secretary to the Society, Rotterdam.

The Ottawa correspondent of the *Times*, writing under date May 19, says: "The Royal Society of Canada, representing all the scientific and learned societies in the Dominion, met to-day. The business transacted included the adoption of a memorial to the Governor-General on the subject of the sixth resolution of the Prime Meridian International Conference of 1884, praying his Excellency's intervention with the home authorities with respect to the unification of nautical, civil, and astronomical time. Evidence was submitted establishing the fact that ship masters, both British and foreign, are almost unanimously in favour of the proposal, and that Canada, not only as a maritime portion of the Empire, but in other respects also, is peculiarly interested in the matter. It is strongly urged that the reform should be adopted so as to come into effect on the first day of the new century, and that, as nautical almanacs are prepared some years in advance, no time should be lost in adapting them to the change."

The Paris correspondent of the *Chemist and Druggist* remarks that there are several pictures of interest to men of science at the Salon of the Champs Elysées this year. The most attractive of these is a decorative panel by Fournier, ordered by the State for the purpose of being placed in Pasteur's old laboratory at the École Normale Supérieure. The centre figure of the panel is an excellent portrait of Pasteur, who is depicted working by gaslight at a table in his laboratory, and the light is made to illuminate his fine features. Before him is a microscope, and he is shown in a reflective attitude as though about to make an entry in an open book that lies before him. Immediately above him is the figure of a woman personifying Science, receiving another, representing suffering humanity, in her arms. On the left are two young doctors in the act of inoculating a patient. On the right is a group of women, one holding forward her baby. A number of appropriate inscriptions appear on the panel.

The *Weekly Weather Report* of the 16th inst. shows that the rainfall of the British Islands since the beginning of the year is deficient in all districts except the north of Scotland. The greatest deficiency is in the Channel Islands, where it amounts to 6·3 inches; in the south-west of England it amounts to 5·7 inches, and in the south of England to 4·5 inches. The severity of the recent drought may be judged by the following low falls in hundredths of an inch between April 17 and May 17, inclusive, in various districts:—Scarborough, 18; Spurn Head, 14; Cambridge, 17; Rothamsted, 8; Loughborough, 7; Oxford 0; London, 4; Dungeness, 10; Holyhead, 15; Prawle Point, 5; Donaghadee, 18; Roches Point, 11; Scilly, 5. The general distribution of barometric pressure over our Islands during the drought has been anticyclonic, with light or moderate north-easterly and easterly winds; while areas of low pressure occasionally passed over the north of Scotland, and occasioned slight falls of rain in the north and west. On the 18th inst., however, a well-marked "V-shaped" depression passed across the northern parts of our Islands, causing rain at many stations, and amounting to half an inch in parts of Scotland.

The rule followed by Irishmen at Donnybrook fair, to hit a head whenever they saw one, seems now to be applied to meteorological instruments. Writing from Edinburgh, Mr. W.

Black says a friend of his recently had his meteorological instruments upset and kicked about by Irish miners working in Lanarkshire. But the exuberance of spirits which led to this destruction is not confined to Irishmen, for Mr. Black says that at Duddingston Loch, some time ago, a number of Bank Holiday savages upset a complete meteorological equipment into the water near which it was installed; while in several northern towns it is necessary to enclose the instruments in iron cages to preserve them from being used as targets by the demon boy. Probably much of the destruction is the result of sheer wantonness, but anthropologists might be able to find evidence that the instruments are considered uncanny, in which case we should have to confess to the survival of the mediæval superstition against meteorology.

MOST workers with Röntgen rays have observed that a photographic plate becomes more or less fluorescent when the rays fall upon it. Mr. W. J. D. Walker informs us that a Paget x x x x x plate used by him fluorised so decidedly, that it made a very fair fluorescent screen, capable of showing coins in a purse, the bones of the fingers, screws and nails in a wooden block, and similar objects.

A NUMBER of excellent Röntgen photographs received from Mr. H. S. Pyne, of King William's College, Isle of Man, show that the Wimshurst machine is capable of producing effects comparable with those given by means of a good induction coil. The machine employed had plates fifteen inches in diameter, and the best results were obtained when the discharge was made intermittent. By this means the tube is rested, and, even with a quarter of an hour's continuous work, the phosphorescent area does not become appreciably warm. A Newton's "focus" tube was used, and the definition of the pictures produced by its radiations is exceedingly good and sharp. All the plates used were "Ilford rapid," with the exception of one, being a "Cadett" lightning. The latter plates Mr. Pyne has found to require the least exposure.

THE peculiar glow exhibited by a "focus" tube working well furnishes a good criterion of efficiency as regards Röntgen rays. A more definite means of comparing the actinic power of the radiation has been produced by Messrs. Reynolds and Branson, Leeds. A small quadrant of aluminium is constructed in concentric terraces, ranging from one millimetre to ten millimetres in thickness. By holding this quadrant between an excited Crookes' tube and a phosphorescent screen, the thickness of aluminium which the rays are capable of traversing can be seen upon the screen; or, by substituting a sensitive plate for the screen, the effect may be photographed. The "X-ray meter," as the quadrant is called, thus furnishes an easy means of comparing the intensity of Röntgen rays emitted by different tubes and by the same tubes at different times.

FROM Prof. A. Battelli and Dr. A. Garbasso, of Pisa, we have received several interesting papers describing their experiments on Röntgen rays. Referring to the discovery that the time of exposure required for taking photographs with these rays can be greatly shortened by placing certain fluorescent substances behind the photographic plate, the authors point out that they described a method of doing this in the January number of *Il Nuovo Cimento*. In some cases Prof. Battelli and Dr. Garbasso obtained good photographs with an exposure of only two seconds. In their paper, experiments were also described proving that Röntgen rays can be reflected (or at any rate scattered) from surfaces, but indicating an absence of refraction. Since the appearance of the above paper, Prof. Battelli has communicated two further papers to the same journal. In the first, the author arrives at the conclusion that Röntgen rays behave as if they emanate from the base of the vacuum tube rather than from the anode or kathode, also that they are emitted even after the discharge in the tube has ceased (as proved by the discharge of an electrified disc in the neighbourhood of the tube). In the second paper, Prof. Battelli deduces that the rays which emanat from the kathode in a vacuum tube possess photographic properties; that their action increases as the rarefaction increases (at least up to $\frac{1}{200}$ mm. of pressure); and that some of the ray are deflected by a magnet, while others are not. It is hence quite permissible to maintain that Röntgen rays exist in the interior of the tube. This view does not contradict the result that the rays *appear* to have their origin at the point where kathodic rays meet with an obstacle. It is easily seen that such an obstacle would act on the rays either as a filter or by scattering them in all directions.

THE various manurial trials conducted on behalf of the County Councils of Cumberland, Durham, and Northumberland in 1895, form the subject of a report by Prof. Somerville, of the Durham College of Science. Results of experiments on turnips, conducted at twelve centres, are considered to give a definite answer to the question as to whether it is the potash, the magnesia, or the salt in kainit that determines its value, its efficacy being attributed to the potash, which is the only substance that has consistently increased the average crop in these trials. No poin has been more clearly demonstrated in the field trials of the last few years than that large dressings of dung or artificial manures d not increase the turnip crop to the extent usually supposed. It argued that they would be more effective if they were applie in small quantities to each crop in the rotation as it came t occupy the land, instead of being, as at present, put into the land, say, every four years, to be exposed to all the wastefu agencies that may operate upon them till the plant food that they contain is exhausted. Manurial reform would seem to be most needed in the case of the artificial manures, since, for the incorporation of dung with the soil, the root-break offers facilities such as are afforded by no other crop in the rotation. The report includes details of experiments with finger-and-toe i turnips, and with *bouillie bordelaise* as a check upon potato disease.

THE report of the field experiments carried out in 1895 by the Agricultural Department of the University College of No: Wales, Bangor, under the auspices of the County Councils of Anglesey, Carnarvon, Denbigh, Flint, and Montgomery, forms a brochure of some fifty pages. The experiments were concerned with the manuring of swedes, of pasture land, and of hay fields, the growth of oats from different quantities of seed, and the effects of various manures on the growth of vegetables. The work was conducted at more than thirty distinct centres, scattered over the five counties, and the question arises as to whether this is not too diffuse an application of energy to afford the best results. It is stated that within the last eleven years the trials "have gone on increasing until the number of centres has almost reached forty." Some of these places are nearly 150 miles apart, and many are far removed from railways. It is, however, correctly understood that these field trials are really intended to serve the purpose of object-lessons, "in which conclusions arrived at elsewhere may be made use of for the benefit of particular districts." There is considerable variation in the results obtained from the use of the same manures when applied to hay and pasture lands in different parts of North Wales. Phosphatic manures have proved the most satisfactory, and of these the most economical manure in the majority of cases was basic slag. The experiments, which must have involved a large amount of work, were conducted by Messrs. T. Winter, Bryner Jones, R. H. Evans, and F. V. Dutton. Every care should be taken to secure exactitude in such reports as this, intended for circulation amongst farmers

We notice that no denomination is given to the weights of seeds in the table on p. 47, though pounds, of course, are intended.

Messrs. Macmillan and Co. have made arrangements for the issue in New York and London of a "Dictionary of Philosophy and Psychology," under the editorial supervision of Professor Baldwin of Princeton University. All the matter in the Dictionary will be original and signed, and the several departments will be entrusted to men most competent to deal with them.

Writing with reference to the diagram published in Nature of February 27 (vol. liii. p. 404), to illustrate the movements of the terrestrial pole determined by Prof. Albrech, Mr. T. W. Kingsmill points out that the irregular variations in the curve are apparently coincident with remarkable seismic disturbances. He therefore suggests that there is a connection between movements of the earth's axis and unusual seismic activity.

We have received two more of the valuable publications of the Geological Survey of Canada, forming Parts B and M of Annual Report, vol. vii. The first of these is a Report on the Kamloops map-sheet of British Columbia, by Dr. G. M. Dawson. It is accompanied by two maps of the area, one strictly geological, the other glacial and economic, and the Report itself contains a number of reproductions of photographs of the district. The rocks of the area range from Cambrian to Tertiary and later, and are described at length; while topographical, meteorological, and mineralogical observations are also recorded. The whole volume consists of over 400 pages. The second is a Report by Mr. R. Chalmers on the surface geology of parts of New Brunswick, Nova Scotia, and Prince Edward Island. Besides minor matters of local interest, it includes discussions on the origin of the Bay of Fundy depression, the glacial striæ of the district, and the destruction of the forests. Several maps accompany the Report, and a photograph of the famous tidal bore in the Petitcodiac River, Bay of Fundy, deserves special mention.

True it is that at the Royal Victoria Hall, in Waterloo Bridge Road, music and mummery occupy a larger share of attention than lectures on scientific subjects. South London audiences have but a mere *penchant* for the generous new wine of science; they reserve their capacities for the variety entertainments. But though the audiences on Tuesday evenings, when scientific discourses are delivered, are very much smaller than on the evenings when a lighter vein predominates, they listen in a way which shows that they appreciate the fare provided for them. And it is satisfactory to know that most of the lecturers are in the front rank of scientific investigators, for this fact may be taken as a guarantee that sound information is imparted. The list of lecturers and subjects given in the report on the work of the Hall during 1895 is most creditable to the energy of Miss Cons, the Secretary, and to the generous spirit of the men of science who gave their services.

Following up the work which resulted in the preparation of the phosphoryl chlorobromides, M. Besson (*Comptes rendus*, May 11), by a similar method, has succeeded in preparing the corresponding thiophosphoryl derivatives. A mixture of hydrobromic acid and thiophosphoryl chloride passed over pumice at 400°–500° C. yields a liquid from which it is possible, by fractional distillation under reduced pressure (60 mm.), to separate both the intermediate chlorobromides. These substances resemble in their general behaviour the corresponding phosphoryl compounds. They undergo partial decomposition when distilled under ordinary atmospheric pressure, and are slowly acted upon by water. The chloromonobromide, ($PSCl_2Br$), has been previously obtained by Michaelis by the action of bromine upon $PSCl_2(OC_2H_5)$, but his product seems to have been impure.

The additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*, ♀) from India, presented by Mr. F. Greswolde-Williams; a Red-fronted Lemur (*Lemur rufifrons*, ♂) from Madagascar, presented by Mr. E. A. Pardoe; a Grison (*Galictis vittata*), a Black Tortoise (*Testudo carbonaria*), a Brazilian Tortoise (*Testudo tabulata*), a Rough Terrapin (*Clemmys punctularia*), two Scorpion Mud Terrapins (*Cinosternon scorpioides*) from South America, presented by Mr. J. J. Quelch; a Lesser Kestrel (*Tinnunculus cenchris*), captured off the coast of Sicily, presented by Mr. J. L. Spaull; a Natal Python (*Python sebæ*, var. *natalensis*), a Ring-hals Snake (*Sepedon hæmachetes*) from South Africa, presented by Mr. W. Champion; a Common Viper (*Vipera berus*), British, presented by Mr. H. L. C. Barret; eight Esquimaux Dogs (*Canis familiaris*), Arctic Regions, deposited; a Pied Crow Shrike (*Strepera graculina*) from Australia, two Whooper Swans (*Cygnus musicus*), European, purchased; two Barbary Wild Sheep (*Ovis tragelaphus*), born in the Gardens.

Erratum.—In the letter entitled "Simple Huyghens' Apparatus for the Optical Lantern," in the issue of Nature for April 9, instead of "a thickness of 1½ inches or more," read "of ½ inch or more."

OUR ASTRONOMICAL COLUMN.

The System of Castor.—A very interesting discovery with regard to this well-known binary star has been made by Dr. Belopolsky (*Bull. Acad. Imp. Sci. St. Petersbourg*, vol. iv. No. 3). In addition to the two luminous bodies, which perform their revolution in a period of about 1000 years, Dr. Belopolsky's observations indicate that the brighter star, α_1 Geminorum, has a dark companion very similar to that of Algol, except that it never produces eclipses. The existence of this dark body was suspected in 1894, and it was fully confirmed by photographs of the spectrum taken at Pulkowa early in the present year, showing periodic changes in the velocity of the star along the line of sight. Thirteen photographs were obtained, and from these the velocities of α_1 Geminorum towards or away from the sun were deduced. Although the available data are insufficient for a complete determination of the orbit, it may be taken to be circular as a first approximation, and a period of revolution of 2·98 days sufficiently accords with the spectroscopic measurements. The proper motion of the system of α_1 is 1·0 geographical mile (=4·6 English miles) per second away from the sun, while the relative orbital velocity is 4·5 geographical miles (20·7 English miles) per second.

Dr. Belopolsky also tabulates the wave-lengths of some of the principal lines in the spectrum of α_1 Geminorum, which somewhat resembles that of Sirius in having broad lines of hydrogen, and many finer lines which are chiefly due to iron. α_2 Geminorum gives a spectrum with less numerous lines.

Efficiency of Photographic Telescopes.—Dr. Isaac Roberts has recently conducted an important series of experiments with the view of ascertaining the relative efficiency of a reflector and of portrait lenses for the delineation of celestial objects (*Monthly Notices*, vol. lvi. p. 372). It has often been asserted that portrait lenses have, by reason of their short focal lengths in relation to their apertures, greater photographic power than instruments of other forms; but this does not accord with Dr. Roberts's experience. A portrait lens of Dallmeyer's latest pattern, 3½ inches aperture and 9½ inches focus, and a 5-inch Cooke patent triplet lens of 19·2 inches focus, were attached with their cameras to the 20-inch reflector, and photographs of the same regions were taken simultaneously with the three instruments. The 5-inch lens was stopped down to a ratio of 1 to 4·8, while the ratio of aperture to focus in the case of the reflector was 1 to 4·9. In three exposures on the region of M. 33 Trianguli, the stars were 3½ times more numerous on the reflector photograph than on the photograph taken with the 5-inch lens in an equal angular area, and 7·8 times more numerous than in the case of the 3½-inch lens. At the same time the reflector photograph showed the nebula more extensively, more clearly depicted, at least two stellar magnitudes denser, and with far more structural details than can be seen on the other photographs.

Similar results were obtained with exposures on other regions, and in all cases the nebulosity shown on the plates taken with the reflector was denser than that registered by the portrait lenses in the approximate ratio of the relative numbers of faint stars shown on plates exposed simultaneously. Figures are also given which demonstrate the superiority of the reflector over the Willard lens, with which Prof. Barnard has obtained such striking photographs.

The experiments seem to point to a practical limit of about 1 to 5 for the ratio of aperture to focus in the construction of instruments for celestial photography. Dr. Roberts further concludes that it is not possible, as is often stated, that a photographic instrument of the portrait lens form can imprint images of nebulæ that are fainter than the faintest star-images imprinted at the same time and under exactly similar conditions.

Solar Photography at Meudon.—In his recent presidential address to the Astronomical Society of France, Dr. Janssen gave a few particulars as to the progress of solar photography at Meudon. The well-known photographs taken some years ago revealed much that was new in regard to the granulation of the photosphere, and as the work has been continued, it has been found that the faculæ, and even the striæ in the penumbra of a sun-spot, have a granular structure like the rest of the solar surface. One can look upon the granule, or small photospheric cloud, as an element of the photosphere just as the cell is that of organic tissues. These granular elements are very small, sometimes being only one or two-tenths of a second in diameter; and exceptionally favourable atmospheric conditions appear to be necessary for their proper investigation.

University Observatories in America.—We learn from *Science* that at the last session of the Illinois Legislature an appropriation was made for the erection and equipment of an observatory for the State University at Champaign. The designs for the building were made, under direction of Prof. Ira O. Baker, by the Architectural Department of the University. The instrumental equipment, consisting of a 12-inch equatorial, a 3-inch combined transit and zenith telescope and a chronograph, will be made by Warner and Swasey, the optical parts being made by Brashear. This makes four universities which have established observatories within the past year, all of which have ordered telescopes from Warner and Swasey, with optical parts by Brashear. The list is as follows: University of Pennsylvania, Philadelphia (18-inch aperture); University of Ohio, Columbus (12-inch aperture); University of Minnesota, Minneapolis (10½-inch aperture); University of Illinois, Champaign (12-inch aperture).

INTERNATIONAL CATALOGUE OF SCIENCE.

We have been requested to print the following circular, which the Royal Society has recently issued to the foreign and other delegates of various nations, now numbering about thirty, whose appointment has been already notified:—

"In anticipation of the forthcoming International Conference to consider the preparation of a catalogue of scientific literature by international co-operation, we are directed to address to you the following:—

"It is proposed that the Conference shall be held at the rooms of the Royal Society, Burlington House, London, *beginning on Tuesday, July* 14, 1896, at 11 a.m.

"One of the earliest acts of this first meeting will be to appoint an organising committee to determine the mode of procedure (including the language or languages to be used at the Conference), the course of business, and the way in which votes shall be recorded on occasions when it will be necessary to have recourse to formal voting.

"The Committee of the Royal Society hopes to be in a position to bring definite proposals before the Conference with regard to its main work. Meanwhile, we are directed to submit to your consideration the following provisional suggestions, and to invite remarks from you upon them:—

"I. That the proposed International Authors and Subject Catalogue of Scientific Literature shall be restricted, in the first instance, to branches of pure science, such as mathematics, astronomy, physics, chemistry, geology, zoology, botany, physiology, and anthropology, to the exclusion of applied sciences, such as engineering, medicine, and the like: the determination of the distinction between pure and applied science being left to the Conference.

"II. That in such an International Catalogue of Science all definite contributions to pure science shall be thoroughly indexed, whether occurring in books, memoirs, &c., treating of pure science, or in those devoted to applied or practical science—in other words, that the catalogue shall not be confined to papers published in certain periodicals, or to books of a certain category.

"III. That with regard to the form of the said Catalogue:—

"(*a*) There shall be a first issue of authors' titles, subject-matter, &c., in the form of *slips* or *cards*, which shall be distributed as speedily and as frequently as possible to subscribers generally.

"(*b*) That a further issue in book form, in a state for use as a permanent work of reference, shall take place at such intervals as may be determined on, parts corresponding to the several sciences being, if found desirable, published separately.

"IV. That, in order to secure the preparation and publication of such an International Catalogue, a Central Bureau shall be established under the control of an International Council.

"V. That the whole of the Catalogue shall be prepared and issued subject to the authority of the International Council, and that any particular undertakings which may be allotted to particular countries, institutions, or persons, shall be subsidiary to the work of the Central Bureau and subject to its control.

"VI. That the cost of preparing and publishing the said Slip- and Book-Catalogues at the Central Bureau during the years 1900–1904, in so far as these are not met by sales, shall be provided for by means of a guarantee fund, and that application be made to governments, learned societies, institutions, and individuals throughout the world, to assist in establishing such a fund.

"The Conference will also have to take into consideration the following matters, among others:—

"(*a*) Supposing that the plan of a Central Bureau is adopted, where shall the Bureau be placed?

"(*b*) The mode of appointment and organisation of the International Council in charge of the Bureau.

"(*c*) The language or languages to be adopted for the Catalogue.

"(*d*) The system of classification to be adopted in the subject index. It is suggested that the decimal system of Dewey may be so amended as to be worthy of adoption.

"There is necessarily the greatest difficulty in estimating the cost of the work in advance, or in forming an opinion as to the extent to which such an enterprise will be self-supporting. It will probably, therefore, be best to raise a guarantee fund covering a period of not less than five years, within which period it will undoubtedly be possible to determine the cost of the enterprise. The annual sum to be thus secured may be approximately estimated at ten thousand pounds.

"We are, your obedient servants,

"M. Foster, Secretary, R.S.
"Rayleigh, Secretary, R.S.
"E. Frankland, Foreign Secretary, R.S."

THE FRENCH UNIVERSITIES.[1]

On March 5 the Chamber of Deputies voted unanimously for a reconstitution of the French universities. In order to understand the object of this important law, it is necessary to recall the circumstances and the legislative proceedings which brought about its adoption.

Until 1875 the faculties of literature, science, law, and medicine existed separately in France, without being united by a single tie, even when four of them (a university, in the acknowledged sense of the word) existed in the same town. In 1875 the National Assembly announced the liberty of higher instruction, permitted the installation of free faculties, and accorded to the group of three faculties (refused to similar groups of the faculties of the State) the title of University. This vote increased at once, by reaction, the force of the movement, which, since the fall of the Empire, claimed unsuccessfully, by means of such men as Guizot, Cousin, Duruy, and Renan, the constitution of State universities. In 1877 a first scheme of law was handed over to M. Waddington, then Minister of Public Instruction, by a Committee of eminent men

1 Condensed from an article in the *Revue de l'Université de Bruxelles*, February 1896.

and jurists, amongst whom were Renan, Taine, Berthelot, and others.

This led to the creation of seven complete universities, to which the nearest separate faculties attached themselves. M. Waddington, after having looked over the scheme, did not ask for a discussion. He thought that universities could not be established before university life had been founded, before the material, scientific, and moral situation of the faculties had been ameliorated. It is in this direction that the reforms were directed.

In 1885, the localities of the faculties having been changed, their scientific instruments being complete, their courses extended, at the cost of great pecuniary sacrifices, the question of universities was again renewed. The Minister of Public Instruction, at this time M. R. Goblet, signed two important resolutions. For each group of faculties there was instituted a general Council composed of two delegates of each faculty, with extended functions for academic, scientific, administrative, financial and disciplinary matters. The Rector of the Academy received the presidency. The ordinary life of the faculties of the same town was thus created. Each one of the faculties received, besides, confirmation of the right that they possessed since their creation, but which was repealed in deed to receive endowments, legacies and relief.

The faculties became therefore civil persons, but their grouping remained extra-legal, and had no judicial unity. It is in a scheme of law presented to the Senate in 1890 by M. Bourgeois, then Minister of Public Instruction, that the proposition is first made to confer the civil personality and the name of University on the groups, comprising at least the four faculties of law, literature, science and medicine, and to give to the universities the autonomy of their budget, by abandoning to them all the receipts which they effected (right of inscription, of study, revenues) for covering their expenses, with the help of a State subsidy. This project, rather badly received by the Senate, was sent back to a Commission, which very soon gave up its examination. It met with the strong opposition of the senators who represented the towns of the little groups of two or three faculties, which could not, by the terms of the project, pretend to the rank of University.

In spite of this repulse, the Minister of Public Instruction, and especially M. Liard, the eminent Director of Higher Instruction, were not discouraged. They succeeded in having inserted in the Finance Law of April 28, 1893, an article (No. 72) which conferred civil personality on the faculties in the same academic resort. The Senate, averse to the project of 1890, accepted the provision of 1893 by 212 votes against 56. Thus new progress was made.

Nevertheless, as it became more evident that the Senate would never consent to sacrifice the little groups of faculties, the partisans of the universities had to content themselves, in order to obtain anything, with demanding less.

In 1895, M. R. Poincaré presented the proposition which has just been voted for by the Chamber, and which he defended as Reporter, at the side of his successor in Public Instruction, M. Combes.

Briefly, in the terms of the project, the bodies of faculties, instituted in 1893, take the name of University; the general councils of the faculties, created in 1885, become councils of the university. In 1898 each faculty will have a budget of its own.

This arrangement has its importance, for it confers on certain groups of the university considerable receipts—646,000 francs at Paris, 105,000 at Bordeaux, 128,000 at Lyons, 83,000 at Lille.

By the vote of the Chamber, and that of the Senate, the universities, suppressed by the Revolution, will be reconstituted in France and endowed with civil personification. The new law is, on the other hand, but the result of the long evolution commenced twenty years ago. It perpetuates results already attained, and so little contested, that in 1889 M. Gréard, in his inaugural discourse at the Sorbonne, talked of the University of Paris, and the new buildings of the Faculties of Lille bear the inscription "University of Lille."

It is certainly to be regretted that the proposal of 1890 was not adoped. Real universities must include four faculties. And, as the Rector of the Catholic Institute of Paris, M. d'Hulst, has said at the Chamber, it is a delusion to call the union of only two or three faculties a university. It may be presumed that the incomplete groups, in order to maintain their new name and the concurrence of the complete groups, will try to give themselves the faculties which are wanting. If they do not succeed, they will remain, of necessity, in the shade; and it is better, in short, to see the faculties of Paris become a university, even if those of Clermont-Fenaud receive the same title, than to see the ambiguous situation, created in 1885, continued.

There are fifteen groups of faculties in France; there would, therefore, be fifteen universities, of which seven are complete: Paris, Lyons, Bordeaux, Toulouse, Montpellier, Lille, and Nancy. It is to be remarked that the southern half of the country will possess four of the seven universities. The incomplete universities are Aix-Marseilles, Rennes, Caen, Poitiers, Grenoble, Dijon (law, science, and literature), Clermont, and Besançon (science and literature).

The above-mentioned towns, Clermont and Besançon excepted, contain a preparatory school of medicine. Many of these schools will probably be turned into faculties.

NATIONAL ACADEMY OF SCIENCES.—WASHINGTON MEETING.

THE recent annual meeting of the National Academy of Sciences in Washington brought together an unusual number of members; and the papers read during the first three days of the meeting included several of special interest and value.

Naturally the Röntgen rays have been the prominent topic, and it is fortunate that most of the successful investigators have attended and read papers, or participated in the discussions. Some errors which have gained credence and wide publication have been corrected, and perhaps the most satisfactory feature of the discussion has been the elimination of these errors, and the correction of too hasty generalisation from experiments conducted without sufficient care.

What the rays are Prof. Rowland frankly admits we do not know, nor are we perceptibly nearer a solution of the problem than when Röntgen first launched his epoch-making essay.

Prof. Rowland presented to the Academy some notes on the rays, in which he said in part that investigators of the source of these rays generally overlook the fact that electrical currents are almost invariably accompanied by oscillations, so that each pole is alternately anode and kathode, thus vitiating any generalisations as to the anode or the kathode being the source of the rays. He mentioned that the rays are developed to the greatest extent when the kathode rays fall on the anode, and hence a kathode ground to a reflecting surface focused on the anode gives the best results. This fact is utilised in the construction of the "focus-tubes" now largly used in Röntgen photography.

Prof. Rowland has obtained good results by using perfect vacuum tubes in which the electrodes are brought within one millimetre of each other. The source of rays here is less than 1/1000 of an inch in diameter. This throws a shadow with remarkably sharp outline, being less than 1/1000 inch. The width of the image gives the limit of wave-length—if it is indeed an undulation, and not the projection of material particles—not greater than 1/8 the length of waves of yellow light.

A paper on the source of the Röntgen rays was read by Prof. A. A. Michelson and S. W. Stratton. Prof. Michelson maintains that these rays are not essentially different from those of Lenard. The latter produce their effect mostly within the tube, the former without; but Lenard also found an actinic effect outside the tube. He also brought forward evidence to show that Röntgen rays radiate in all directions from the surface first encountered by the kathode rays, and do not start from the anode.

Prof. A. M. Mayer read several papers. He showed that investigations of polarisation of these rays must be made with some very thin substance of low density, herapathite being the best; but this substance, which is an iodo-sulphate of quinine, is difficult to obtain. He described the process, already communicated by him to NATURE (April 2). On using plates of herapathite with three different exposures of half-hour, one hour, and three and a half hours, no polarising effect was produced. He remarked that calc-spar was utterly unavailable as a test of polarisation of these rays, because it could not be procured of sufficient thinness for the rays to penetrate, Hence the researches of some experimenters, though widely published, were of no value whatever. He has determined the density of herapathite with great accuracy and by repeated

experiments, and finds it much smaller than Herapath did, namely, 1·557.

Prof. Mayer also gave formulæ of transmission of Röntgen rays through glass, tourmaline and herapathite. To determine whether rays just go through or nearly go through, he uses a wire grating which will appear in the picture if rays go through. Transmission depends on the thickness of the glass plus the time of exposure. Glass of various thickness is used, one plate being superposed upon another in successive gradations. The eye cannot distinguish a difference less than about 1/100, and this is what passes through glass of five millimetres thickness. If we begin with glass 1/10 millimetre thick, it absorbs 1/10 of the rays, and each superposed 1/10 millimetre absorbs 1/10 of the residue, so that the formula in general is $I' = Ia^t$. It is evident, therefore, that there is no constant ratio of comparison of absorption by different materials, because the successive powers of "a" have not the same ratio to each other that the first powers have. In the case of herapathite the absorption (a) is found to be ·9382, so the formula becomes $I' = I \cdot 9382^t$. The formula for tourmaline is the same as for glass, so tourmaline is a very imperfect substance to use.

Prof. Ogden N. Rood read a paper detailing his experiments in reflecting the X-rays, which have enabled him to reflect 1/260th part of the rays incident on platinum at an angle of 45° (see NATURE, April 30, p. 614).

Prof. Arthur W. Wright read a paper on the relative permeability of magnesium and aluminium by Röntgen rays. He reported experiments showing that magnesium is much more permeable than aluminium. Magnesium is also more readily wrought than aluminium, thus making it much more desirable to use in the investigation of these rays.

Prof. T. J. J. See, of Chicago University, read a paper on double stars, giving results of three years' observations. He concludes that at the end of 115 years we know accurately only forty; that there is only evidence of disturbing bodies in a few cases, which are indecisive; that great eccentricity of orbit prevails, the average being twelve times as much as that of planetary orbits, and that the law of gravity is rendered probable and may be hereafter confirmed by spectroscopic investigation.

Among other papers read are:—The geological efficacy of alkali carbonate solutions, by E. W. Hilgard, read by G. Brown Goode; on the colour relations of atoms, ions, and molecules, by M. Carey Lea, read by Ira Remsen; on the characters of the Otocœlidæ, by E. D. Cope; on the determination of the coefficient of expansion of Jessop's steel, between the limits of 0° C. and 64° C., by the interferential method, by E. W. Morley and Wm. A. Rogers; on a remarkable new family of deep-sea Cephalopods (*Opistotenthis*), and its bearing on molluscan morphology, and on the question of the molluscan archetype, by A. E. Verrill; on *Pithecanthropus erectus* from the Tertiary of Java, which was discovered by Dubois in 1895, by Prof. Marsh; on the separate measurement, by the interferential method, of the heating effect of pure radiations and of an envelope of heated air, by Wm. A. Rogers; judgment in sensation and perception, by J. W. Powell; exhibition of a linkage whose motion shows the laws of refraction of light, by A. M. Mayer; location in Paris of the dwelling of Malus, in which he made the discovery of the polarisation of light by reflection, by A. M. Mayer. Ira Remsen read a paper on some studies in chemical equilibrium, and several papers were read by title.

The Academy adjourned to meet at New York, November 17, 1896. WM. H. HALE.

THE MANUFACTURE OF ARTIFICIAL SILK.

LANCASHIRE is on the eve of some important expansions of the textile trades, for, from an interesting article in the *Times*, it appears that the manufacture of artificial silk from wood pulp will shortly be added to her industries. At present the wood-silk comes from France, large works having been established at Besançon under patents granted to Count Hilaire de Chardonnet, who discovered the process, and first established in 1893 the fact that it might be made into a commercial success. The demand for the new commodity increased so considerably that the idea of introducing its manufacture into England was mooted, with the result that a number of silk and cotton manufacturers met to discuss the question, and finally sent out to Besançon a deputation, consisting of some of their own number, an engineer, a chemist, and a lawyer, to investigate the subject thoroughly. This was done, and the outlook was found to be so promising that certain concessions have been secured and a company is now in process of formation, and, to begin with, a factory, which will cost £30,000, is to be built near to Manchester for the manufacture of artificial silk yarn from wood pulp, for sale to weavers, who will work it up by means of their existing machinery. The way in which wood pulp can be converted into silk yarn is explained in the *Times*. The pulp, thoroughly cleansed, and looking very much like thick gum, is put in cylinders, from which it is forced by pneumatic pressure into pipes passing into the spinning department. Here the machinery looks like that employed in Lancashire spinning sheds, except that one of the pipes referred to runs along each set of machines. These pipes are supplied with small taps, fixed close together, and each tap has a glass tube, about the size of a gasburner, at the extreme point of which is a minute aperture through which the filaments pass. These glass tubes are known as "glass silkworms," and some 12,000 of them are in use in the factory at Besançon. The effect of the pneumatic pressure in the cylinders referred to above is to force the liquid matter not only along the iron tubes, but also, when the small taps are turned on, through each of the glass silkworms. It appears there is a scarcely perceptible globule. This a girl touches with her thumb, to which it adheres, and she draws out an almost invisible filament, which she passes through the guides and on to the bobbin. Then, one by one, she takes eight, ten, or twelve other such filaments, according to the thickness of the thread to be made, and passes them through the same guides and on to the same bobbin. This done, she presses them together with her thumb and forefinger, at a certain point between the glass silkworms and the guides. Not only do they adhere, but thenceforward the filaments will continue to meet and adhere at that point, however long the machinery may be kept running. In this way the whole frame will soon be set at work, the threads not breaking until the bobbin is full, when they break automatically, while they are all of a uniform thickness. The new product is said to take dye much more readily than the natural silk. The chief difference in appearance between the natural and the artificial silk is in the greater lustre of the latter. The success already secured by the new process in France is such that the introduction of the industry into Lancashire is expected to produce something like revolution in the conditions of trade there, not only by bringing into existence a new occupation, but also by finding more work for a good deal of the weaving machinery that is now only partially employed.

A THEORY OF THE X-RAYS.[1]

THE principal facts, which any satisfactory theory of the X-rays is called upon to explain, may be summarised as follows:

(1) The production of the rays by electric impulse, at the kathode,[2] in a highly exhausted enclosure.

(2) Propagation in straight lines and absence of interference, reflection, refraction and polarisation.

(3) The importance of density of the medium as the determining factor in the transmission of the rays.

(4) The production of fluorescence and actinic effects, and the action on electrified conductors.

Two theories have been proposed to account for these remarkable phenomena: (1) the theory of longitudinal waves; (2) the theory of projected particles.

In reference to the first theory it may be said that unless it is proved that an oscillatory discharge is essential to the production of the X-rays, there can be no reason for supposing that these rays are of a periodic nature—that they are wave-motion as commonly understood. The absence of interference, reflection and refraction is also a very formidable difficulty. Attempts have been made to account for the absence of these invariable accompaniments of every known form of wave-motion, but, as I think, with very indifferent success.

The most serious difficulty in the second theory is the attempt to explain the passage of the electrified particles of the residual gas (or of the electrode) through the walls of the

[1] From the *American Journal of Science*, April.

[2] Even should further experiment prove that the X-rays proper originat at the first obstruction encountered by the discharge, the fact remains tha this discharge originates at the kathode.

vacuum tube. The query at once arises, if glass is permeable to these particles in virtue of their relatively great velocity, why is it not permeable (in lesser degree) to the same particles moving with smaller velocities? That it is not, is evident from the fact that vacuum tubes retain their high degree of exhaustion unimpaired for years.

In view of these difficulties, I would propose a third theory, which may be called the "ether-vortex" theory.

Let it be supposed that the X-rays are vortices of an intermolecular medium (provisionally, the ether[1]). These vortices are produced at the surface of the kathode, by the negative charge, which forces them out from among the molecules of the kathode.

Let us now apply the tests above mentioned.

According to this theory, an oscillatory discharge, while it may be just as effective as a series of separate impulses, is not essential to the formation of the vortices. The vortices being forced outwards from the surface of the kathode by the negative charge, the effect of the positive charge at the anode would be to drive them in. Hence their appearance at the kathode alone.

One of the greatest puzzles connected with the behaviour of the X-rays is the fact that while they can pass almost unimpeded through air at atmospheric pressure (let alone water, glass, wood, flesh, bone, and metals) *when once outside the enclosure in which they are produced*, they cannot even reach the walls of the enclosure, except there be a very high vacuum within. This problem receives a very natural solution if it be considered that, in order that ether-vortices may result from the electrical impulse, this impulse must be communicated to them; and must not be dissipated in the interchange of molecular charges which accompanies, or rather produces, the discharge at moderate or high pressures.

As exhaustion proceeds there are fewer molecules present to effect this discharge with sufficient rapidity, and as this limit is approached there will be a division of the energy of the electric impulse between the electrified molecules and the ether-vortices, and in the end all the energy of the discharge will be confined to the latter.

The reason for the non-appearance of the rays under ordinary conditions is not that the rays cannot reach the walls of the enclosure or pass through them, but that they cannot form at all. The propagation of vortices in straight lines, the absence of interference phenomena, of reflection, refraction and polarisation, follow from the properties of vortices, and from the absence of anything corresponding to a wave-front. The passage of an ether-vortex through a mass of matter may be compared with a passage of a smoke-ring through a wire gauze screen or a series of such; and as the motion of the rings is more impeded the greater the diameter and the number of wires per unit volume, so, the greater the number and the size of the molecules—that is, the greater the density—the more effective will the medium be in dissipating the energy of the ether-vortices.

The production of fluorescence, actinic effects, and the dissipation of electric charges by light (which is an ether motion) would make it at least probable that similar (though perhaps not identical) effects would be produced by the motions of ether vortices.

Prof. J. J. Thomson has measured the velocity of kathode rays and obtained a result so very far less than the velocity of light as to preclude entirely the idea of there being any connection between the two. If these results can be made to apply to the X-rays, the analogy with the properties of smoke-rings would lead us to expect such a result. The kathode rays have been shown by Lenard to have a considerable range in their properties, depending on the mode of their origin.[2] It seems likely that their velocities are to a considerable extent dependent on the potential and the suddenness of the electrical impulse; and if this were shown to be true of the X-rays, it would be to that extent a confirmation of the theory.

[1] A possible objection occurs to the formation of ether-vortices in a medium which is usually considered free from viscosity; but the fact that vibrating molecules can and do communicate their motions to the surrounding ether shows that the communication of vortex motion may also be possible.
Though not a necessary part of the theory, it may be considered that the expulsion of the ether-vortices is due to an accumulation of ether in the kathode, and this would lend support to the theory that this accumulation is not merely a result of the negative charge, but that this excess of ether is what constitutes the negative charge.

[2] The distinction between the X-rays and the kathode rays appears to be somewhat artificial, and it seems probable that the X-rays are only kathode rays sifted by the various media they have traversed.

The foregoing evidence may be considered scarcely sufficient to entitle the proposition here advocated to the dignity of a theory, but it may at least merit consideration as a working hypothesis which may serve as a guide in future experiment.

ALBERT A. MICHELSON.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Oxford University Junior Scientific Club will hold a conversazione on Tuesday evening, May 26. The rooms and laboratories of the University Museum, Oxford, will be thrown open by permission of the delegates and professors, and apparatus and experiments illustrating recent progress in the various branches of natural science will be exhibited. During the evening Prof. Silvanus P. Thomson will give a lecture on "Luminescence," with demonstrations.

On Tuesday, June 2, before the above Club, Prof. W. Ramsay, F.R.S., will deliver the fifth annual Robert Boyle Lecture, on "Argon and Helium, the two recently discovered gases." The "Robert Boyle Lecture" was instituted in 1892, and the lecturers hitherto have been Sir Henry Acland (1892), Lord Kelvin (1893), Prof. A. Macalister (1894), Prof. A. Crum Brown (1895).

The vacancies in the Public Examinerships in the Honour School of Natural Science have been recently filled up as follows:—In Animal Morphology, Prof. E. Ray Lankester and Mr. Adam Sedgwick; in Botany, Prof. D. H. Scott and Mr. R. W. Phillips; in Geology, Prof. A. H. Green and Mr. J. E. Marr; in Physics, Mr. R. E. Baynes; in Chemistry, Prof. W. Ramsay; and in Animal Physiology, Prof. C. S. Sherrington.

The Scholarships and Exhibitions advertised for proficiency in Natural Science are not numerous this year. Merton and New College offer each one, the examination to be held conjointly by the two colleges at the end of June. Magdalen offers one or more Demyships in Natural Science for competition in October, and the Delegacy of Non-Collegiate Students offers a scholarship for Chemistry. There seems to be a tendency at the present time to curtail the number of scholarships in Natural Science.

The Hope Professor of Zoology is giving a course of public lectures at the Museum, on the Hope Collections. The second lecture of the series will be given on Wednesday, May 27, at 2.30 p.m.

Prof. H. A. Miers, F.R.S., Waynflete Professor of Mineralogy, gave his inaugural lecture at the University Museum on Wednesday last.

A Decree will be proposed on the 26th inst. providing for the enlargement and alteration of certain rooms in the University Museum, in order that they may be adapted to the purposes of the Professor of Mineralogy.

Mr. G. F. Scott Elliot gave a lecture to the Ashmolean Society last Monday, on the race elements of South Africa.

CAMBRIDGE.—The dates of the examinations for entrance scholarships and exhibitions in Natural Science at the several colleges during the next academical year, have been announced as follows:—St. John's and Trinity, November 3, 1896; Pembroke, Caius, King's, Jesus, Christ's, and Emmanuel, November 17, 1896; Peterhouse and Sidney, Clare and Trinity Hall, December 8, 1896; Downing, April 20, 1897. The subjects are in General Chemistry, Physics, Zoology, Botany, Geology, and Physiology, two or more sciences being required. Application for particulars should be made to the respective tutors some weeks before the date of the examination. The yearly value of the scholarships varies from £80 to £40.

Vacancies for students of Biology at the University tables in the Zoological Stations of Naples and Plymouth are announced. Applications to occupy these are to be sent to Prof. Newton by May 27.

THE University of Utrecht will celebrate the 260th anniversary of its foundation on June 22 and five following days.

MR. JOHN H. ROCKEFELLER has given to Vassar College (women's) 100,000 dols. for a new building, to be either dormitory or recitation hall.

MR. ANDREW CARNEGIE has given to the city of Duquesne, Iowa, a library, gymnasium, and public bath. The buildings are to cost 150,000 dols.

The following are among recent appointments:—Dr. Otto Fischer to be Extraordinary Professor of Physiological Physics at Leipzig; Dr. Albert P. Brubaker to be Assistant Professor of Hygiene in Jefferson College, Philadelphia; Dr. E. B. Sangree to be Professor of Pathology and Bacteriology in the Vanderbilt University, Nashville, Tenn.

The new buildings at Owen's School for boys, Islington, which were recently opened by the Master of the Brewers' Company, include some new class-rooms for the teaching of practical science. There is a good science lecture-room, as well as physical and chemical laboratories, both well arranged and equipped. A new art room has also been added. The Brewers' Company have provided the funds for building, and the London Technical Education Board those for furnishing.

The will of Mr. H. W. Massey, of Toronto, contains numerous bequests to charities and educational institutions. Among the latter are 50,000 dols. to the American University at Washington, for a building to bear his name; 10,000 dols. to the Alma Ladies' School at St. Thomas; 100,000 dols. to the University of Mount Allison at Sackville, N.B.; 50,000 dols. to the Wesleyan Theological College at Montreal; 200,000 dols. to the University of Victoria, Toronto; 100,000 dols. to the Wesleyan College of Winnipeg, Manitoba.

We learn from the *Lancet* that Glasgow University is to receive under the will of the late Dr. John Grieve the sum of £8000, which is to be applied at the discretion of the court to the foundation of a lectureship, fellowship, or scholarship. The present demand for teaching in the subject of public health is very inadequately met by the existing laboratory arrangements, and the University Court has decided to equip a temporary laboratory until more satisfactory permanent dispositions are possible. Some recent communications with possible benefactors of the University render it probable that a lectureship in geology will shortly be instituted.

As we reported in our issue of February 20 of this year, it was decided by the County Council of Hampshire that the Finance and Technical Education Committees should meet together and report to the next meeting of the Council their opinion upon the manner in which the balance remaining after the annual expenditure on technical education had been defrayed, should be dealt with. At the meeting of the Council held on Monday, the 11th inst., the joint Committees reported that as an Education Bill had been introduced into Parliament dealing with the Local Taxation (Customs and Excise) Duties, they were of opinion that it would be undesirable to proceed with their deliberations. The report of the Technical Education Committee showed that good work had been done in the county during the past session.

On Saturday, May 2, the new grounds of Columbia University were dedicated, and the corner-stones of Physics Hall and Schermerhorn Hall were laid. A large and distinguished company gathered to honour the events, among whom were the Governor of the State and the Mayor of the City of New York. Congratulations were sent by the President of the United States. The new grounds comprise about seventeen acres, commanding a fine view of the Hudson, and very near to and in sight of the tomb of General Grant. The site is that of the Battle of Harlem, fought September 16, 1776. On this site a group of buildings are now rising, which will provide admirably for the University, giving it facilities unrivalled by any other in America. Its endowment also places it in the front rank. The University has productive property in New York City valued at twelve million dollars, besides large endowments of personal property. Several of the new buildings are gifts—the library from the President of the University, Seth Low, Schermerhorn Hall from William C. Schermerhorn, and the Havemeyer building from the Havemeyer family. University Hall is to be built by gifts from alumni of the University.

The Johns Hopkins University is only twenty years old, yet as regards excellence of work it ranks high among the leading universities in the world. A little brochure containing an account of the constitution and growth of the University has been published in commemoration of the recent twentieth anniversary. The fact that contributions amounting to more than a million of dollars have been received, is an indication that the foundation is firmly established in the confidence of the public. Nearly three thousand students have been instructed; three hundred of the graduates have been teachers in universities, colleges, and high schools, and altogether eight hundred persons who have been pupils of the University have been engaged in teaching; in fact, nearly every university and college in America numbers among its faculty a student of Johns Hopkins University. Since its opening, the University has encouraged the publication of the results of advanced scientific research. Several journals have been regularly maintained, and support has been given to many separate works. Among the most important serial publications are the *American Journal of Mathematics*, *American Chemical Journal*, *American Journal of Philology*, *Studies from the Biological Laboratory*, *Memoirs from the Biological Laboratory*, *Journal of Experimental Medicine*, and the *Johns Hopkins University Circulars*. Many separate publications have also been issued under the auspices, or with the aid, of the University, among the most noteworthy of these being Prof. Rowland's "Photographs of the Normal Solar Spectrum," "The Oyster in Maryland" (a publication in popular form of Prof. Brooks' investigation of the oyster and its relation to interests of Maryland), "Embryology of Insects and Arachnids," by Adam T. Bruce, "Geology and Physical Features of Maryland," by G. H. Williams and W. B Clark, Bulletins and Reports of various departments of the Johns Hopkins Hospital, and a number of topographical and geological maps. For the study of the marine fauna of the Chesapeake region, including the oyster, the Chesapeake Zoological Laboratory, or Marine Station, was instituted in 1878, and a considerable sum of money annually appropriated for its maintenance. Further, the University annually nominates a scholar to occupy a table at Wood's Holl Biological Laboratory, for the prosecution of biological investigation. Thus in a variety of ways the University has fostered original research and sound instruction, and has therefore contributed to the welfare of Baltimore and the advancement of science.

SCIENTIFIC SERIALS.

American Meteorological Journal, April 1896.—A speculation in topographical climatology, by Prof. W. M. Davis. The author refers to certain relations between existing topographic features and climatic conditions, the study of which enable us to infer the vanished climates of the past by means of their still-preserved topographic products. He discusses at some length the records of arid and humid climates, the consequences of various glacial theories, &c., and suggests an exploration of the most critical regions by well-trained topographical climatologists, with the points at issue clearly in mind.—The new meteorological observatory on the Brocken, by A. L Rotch. This observatory has an elevation of 3750 feet above the sea and is the highest mountain in Northern Germany. Observations, with some interruptions, were made between 1836 and 1869, and have now been resumed under the superintendence of the Prussian Meteorological Institute. The greatest difficulty in securing continuous observations is the frost, owing to which an anemometer cannot be kept in action, and much trouble is experienced with thermometers and rain-gauges; nevertheless, in addition to automatic records, direct observations are made thrice daily, from which important contributions will be added to our knowledge of the upper air. Further particulars of the work at this station will be found in *Die Natur* of the 26th ult. by Herr Koch, the Superintendent.

Bollettino della Società Sismologica Italiana, vol. i., 1896, No. 10 and 11.—Summary of the principal eruption phenomena in Sicily and the adjacent islands during the four months September to December, 1895, by S. Arcidiacono. For the whole year (1895) the following summary is given. Etna was covered by clouds on forty-six days; of the remainder, it was in a state of "emanation" on 172 days, and in a "strombolian" condition on 147 days. In Vulcano, Stromboli, and Salsi di Paternò, no change has occurred except that, on March 29, Stromboli passed from the normal to the explosive phase, at the same time a sensible earthquake was felt at several places in Calabria. On a new type of seismometrograph, by G. Agamennone. The instrument consists of a pendulum of mass 200 kg. and length 16 metres, whose movements are magnified by the light horizontal lines at right angles to one another. When the first tremor occurs, the velocity of the strip of paper is increased from about 30 cm. per hour to about 5 mm. per second. The instrument is installed in the Central Meteorological and Geodynamical Office at Rome.—Notices of Italian earthquakes (August-October 1895), the most important being the Adriatic earthquake of August 9.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, May 8.—Captain Abney, President, in the chair.—Messrs. Frith and Rogers read a paper on the true resistance of the electric arc. It was pointed out by Prof. Ayrton, at the British Association meeting at Ipswich, that if the "true resistance" of an arc is defined as the ratio of a small increase of the P.D. between the carbons to the corresponding change in the current, it follows that this "true resistance" must be a negative quantity. In order to measure the "true resistance" without appreciably altering the form of the carbons, &c., the authors superpose a small alternating current on the main continuous current. The arc lamp employed was adjusted by hand, and the arc length was measured by projecting an image of the arc by means of a lens. The main (continuous) current and P.D. were measured by a Weston ammeter and voltmeter, while the auxiliary alternating current was measured by means of an air transformer and an electrostatic voltmeter. The authors find that between the limits employed the magnitude of the alternating current did not influence the results obtained for the resistance of the arc. The frequency, so long as it lies between the limits 250 – 7 complete alternations per second, and the wave form, do not influence the resistance, since the same results were obtained with a Pyke and Harris alternator, a Ferranti alternator, a Gramme alternator, and a Mordey transformer. For each make of carbon examined, four combinations were used :— + cored, – cored : + cored, – solid ; + solid, – cored ; + solid, – solid. The general characteristic of the curves obtained is that for the + solid, – solid combination the "true resistance" is always negative ; while for + cored, – cored it is always positive ; the other curves lying between these two extremes, those which have the + carbon solid always being more negative than those which have the + carbon cored. In the case of the curves showing, for solid carbons, the relation between the resistance of the arc and the P.D. between the carbons, the current being constant (10 amperes), a minimum (maximum negative) value for the resistance occurs at about 55 volts. With combinations having a cored positive this minimum becomes more strongly marked, and occurs at a lower voltage. The authors find that for cored carbons the position of this minimum is closely connected with the presence or absence of the dark space in the arc. For points on the curve to the right of the minimum point, the dark space is absent ; while for points to the left of the minimum, the dark space is always present. It was found that the effect of using as the + carbon a Carré carbon in which the core had been bored out, was to obtain a curve closely resembling that obtained when both carbons were solid. On filling this hollow carbon with plaster of Paris or kaolin, the resistance of the arc became positive. The above experiments were made with the + carbon uppermost ; other experiments, made with the arc inverted, showed that with solid carbons the resistance is not appreciably altered by inverting the arc. With cored carbons, however, the resistance, as well as the physical character of the arc, is altered ; since, on inversion, the dark space disappears, and the resistance considerably diminishes. If, however, the conditions under which the arc is burning are such that the dark space is absent, then inverting the arc does not alter the resistance. Attempts were made to measure the "true resistance" of a direct current hissing arc, but it was found that, even with the alternator at rest, there was a large deflection of the electrometer, showing that the current through a hissing arc was oscillatory. In order to elucidate the marked difference between their results for cored carbons and those deduced from Mrs. Ayrton's curves, the authors have made a series of measurements at low frequencies. They find that there is a critical frequency above which the resistance has a positive value which is independent of the frequency, and below which it has a negative value, this critical frequency lying between 7·5 and 0. In order to investigate the sign of the resistance at low frequencies, the vibrations of the needles of the ammeter and voltmeter were made use of. By an arrangement of mirrors, the needles and scales of both instruments could be observed simultaneously. In this way it could be seen whether the two needles were, at any instant, vibrating in the same or in opposite directions. If the needles vibrate in the same phase, *i.e.* if an increase of P.D. is accompanied by an increase of current, then the resistance must be positive ; while if they are vibrating out of phase, *i.e.* if an increase of P.D. is accompanied by a decrease in current, then the resistance is negative. An attempt to run the arc off a continuous-current dynamo failed, since even with the alternator at rest the electrometer showed a large deflection, evidently due to the oscillation of the current, owing to the commutator of the dynamo having a finite number of segments. Prof. A. Gray doubted whether it was right to give the name "true resistance" of the arc to the slope of the curve connecting the potential difference (V) and the current (A). The authors' method of deducing $\delta V/\delta A$ was only true if the curve was a straight line ; while in the case of the arc, E and a may both vary with the current. Mrs. Ayrton said, that with reference to the question of the existence of a back E.M.F. the evidence tended to show that it did not exist. By using an exploring carbon, no constant back E.M.F would be found. Prof. Ayrton said, that considering the arc as consisting of a back E.M.F. and a resistance, it was necessary to separate these two. Simply obtaining one value of the P.D. and the current was of no assistance in solving this question, but a series of values had to be taken. By taking the change in P.D and current sufficiently small, the curve over the range considered was practically straight. It was curious to note that as long as observers obtained a positive value for the resistance of the arc, no fault was found with the method ; but that now a negative value was found, the accuracy of this method was questioned. If a back E.M.F. does really exist, then it follows that the arc must have a negative resistance. Mr. Frith has shown why some people have got positive and some negative values for the resistance of the arc, and also that with an alternating current you may get either one or the other. Mr. Tremlett Carter asked if the fact that the arc had a negative resistance did not imply a back E.M.F. in order that the arc might be stable. If so, was a negative resistance such an absurdity? Mr. Campbell said he was very pleased to see that the authors had applied a method which he (Mr. Campbell) had suggested for measuring pulsating currents. If a pulsating current, such as could be obtained by means of a make and break, were passed through a thermopile, you would get a back E.M.F. ; while if an alternating current were employed, you would not. Mr. Frith, in his reply, said that he had *defined* the "true resistance" as dV/dA. Mrs. Ayrton has shown that an arc will not run unless a certain resistance is placed in series with it ; this resistance must be numerically equal to the negative resistance of the arc itself. Prof. Ayrton said Mr. Frith's remarks as to the cause of the want of stability of an arc without outside resistance, were most suggestive. The Chairman (Captain Abney) said he did not like the expression P.D. He suggested the employment of photography to facilitate the accurate registration of the instrument readings. The further discussion on the paper was adjourned to the next meeting on May 22.

Mathematical Society, April 23.—Major MacMahon, R.A., F.R.S., President, in the chair.—The President communicated a portion of the following abstract of a paper by Prof. W. Burnside, F.R.S., on the isomorphism of a group with itself. A one-to-one correspondence between the operations of a group, which leaves the multiplication table of the group unaltered, is spoken of as an isomorphism of the group with itself. Such a correspondence may clearly be represented as a substitution performed on the symbols of the operations of the group, *i.e.* the isomorphism may itself be regarded as an operation, and the totality of the isomorphisms of a given group will themselves form a group. This group is known as the "group of isomorphisms" of the given group. The only general theorems connected with the isomorphism of a group with itself hitherto published are due to Herr O. Hölder[1] and Herr G. Frobenius.[2] In the first part of the present paper I have reproduced such of the definitions due to Herren Hölder and Frobenius as are necessary to render it self-contained, and also one fundamental theorem. An isomorphism is defined to be cogredient or contragredient according as it can or cannot be obtained by transforming all the operations of the group by one of themselves. The theorem is that the cogredient isomorphisms form a self-conjugate sub-group of the complete group of isomorphisms. A definition, due to Herr Frobenius, involving an important new conception, is that of a characteristic sub-group. It is as follows. If a sub-group of a given group is transformed into itself by every isomorphism of which the given group is capable, the sub-group is called a characteristic sub-group. In the second part I have first

[1] *Cf.* The first ten pages of a memoir with the title "Bildung Zusammengesetzter Gruppen." *Math. Ann.*, xlvi.

[2] *Cf.* Parts of memoirs with titles "Ueber Endliche Gruppen" and "Ueber auflösbare Gruppen II." *Berliner Sitzungsberichte*, 1895.

investigated the conditions under which a group should have no characteristic sub-group. This condition is that the group should be generated by a number of holohedrically isomorphous simple groups, such that every operation of any one of them is permutable with every operation of all the rest; or, in the phraseology of Herr Hölder, the group must be the direct product of a number of holohedrically isomorphous simple groups. The following theorem is then proved. If G is a group which has no characteristic sub-group, and if R is the group of greatest order that contains G self-conjugately, while at the same time no operation contained in R, and not in G, is permutable with every operation of G; then the group R admits of no contragredient isomorphisms, and contains no self-conjugate operation except identity. A special case of this theorem is that the group defined by the congruences

$$\begin{aligned} x_1^1 &\equiv \alpha_{11}x_1 + \alpha_{12}x_2 + \ \ldots \ + \alpha_{1n}x_n + \beta_1, \\ x_2^1 &\equiv \alpha_{21}x_1 + \alpha_{22}x_2 + \ \ldots \ + \alpha_{2n}x_n + \beta_2, \quad (\text{Mod. } \lambda, \text{ prime}) \\ &\ldots\ldots\ldots\ldots \\ x_n^1 &\equiv \alpha_{n1}x_1 + \alpha_{n2}x_2 + \ \ldots \ + \alpha_{nn}x_n + \beta_n, \end{aligned}$$

dmits only cogredient isomorphisms. In the third part I consider the group of isomorphisms of certain simple groups, some of whose properties I have already dealt with in vol. xxv. of the Society's *Proceedings*. For the simple group of order $2^n(2^{2n}-1)$ there defined, I show that the order of the group R of isomorphisms is $2^n(2^{2n}-1)n$, and that if H is the group of cogredient isomorphisms, the factor group R/H is a cyclical group of order n. For the simple groups of order $\frac{1}{2}\lambda^n(\lambda^{2n}-1)$, λ an odd prime, it is shown that the order of the group R of isomorphisms is $\lambda^n(\lambda^{2n}-1)n$, the factor group R/H being the direct product of cyclical groups of orders 2 and n. The latter class includes as a special case, $(\lambda^n = 3^2)$, the alternating group of six symbols. In Herr Hölder's paper, referred to above, the isomorphisms of the alternating group are dealt with, and, as compared with all other degrees, it is found that the alternating group of degree 6 behaves exceptionally, and requires rather elaborate treatment. There seems, however, to be no reason for regarding the alternating groups of different degrees as a set of groups which are characterised by common group-properties in the same way, for instance, as the groups of the modular equation for different prime transformations are; and this view is borne out by the fact that there is nothing exceptional in the behaviour of the alternating group of degree 6 when regarded as one of the class of groups here considered. —The President also read an abstract of a paper on division of the Lemniscate, by Prof. G. B. Mathews.—Dr. Hobson, F.R.S., read a paper on some general formulæ for the potentials of ellipsoids, shells, and discs.—The President offered some remarks on the compensation for difference of capital in gambling *à outrance*, being a contribution to the theory of the "Duration of Play."—Mr. Basset, F.R.S., read a paper on the stability of a frictionless liquid and the theory of critical planes. In the theory of the stability of the steady motion of a frictionless liquid which is bounded by the parallel planes $y=0$ and $y=a$, the disturbed motion depends upon the equation

$$(n/k + U)(d^2v/dy^2 - k^2v) = vd^2U/dy^2 \quad . \quad . \quad . \quad . \quad (1)$$

The usual process of solution fails whenever there is a plane, called a *critical* plane, at which $n/k + U = 0$, and the object of this paper is to examine the nature of the solution when such a plane exists. In steady motion $U = \phi(y)$, where ϕ is a given function; and if a critical plane exists, $-n/k = \phi(c)$, which determines the relation between the time-constant n and the wave-constant k, provided a *real* value of c can be found which lies between 0 and a. The integral of (1) is of the form

$$v = \mathrm{A}f_1(y) + \mathrm{B}f_2(y).$$

The boundary conditions require that $v=0$ when $y=0$ and $y=a$. At a critical plane $d^2U/dy^2=0$ or $v=0$. If the first condition is satisfied, and if neither of the functions f become infinite between $y=0$ and $y=a$, the boundary conditions enable the constants A and B to be eliminated, which leads to a relation of the form $F(a, k, c)=0$, and the conditions for the existence of a critical plane require that this equation should furnish at least one *real* value of c lying between 0 and a. But if one of the functions—say f_2—becomes infinite between the limits, $B=0$, and the boundary conditions cannot usually be satisfied, in which case a critical plane cannot exist. When the form of U is such that d^2U/dy^2 does not vanish when $y=c$, a critical plane cannot exist except in very special circumstances. The paper concludes by showing that the particular solutions obtained by the hypothesis that x and t enter into the solution in the form of the factor $\epsilon^{\iota kx+\iota nt}$ can always be generalised by Fourier's theorem, so as to include every possible disturbance which does not violate the boundary conditions. The author and Mr. Love, F.R.S., joined in a discussion on the subject of the communication.

Geological Society, April 29.—Dr. Henry Hicks, F.R.S., President, in the chair.—Descriptions of new fossils from the carboniferous limestone. (1) On *Pemmatites constipatus*, sp. nov., a lithistid sponge. (2) On *Palæacis humilis*, sp. nov., a new perforate coral; with remarks on the genus. (3) On the jaw-apparatus of an Annelid, *Eunicites Reidii*, sp. nov., by Dr. G. Hinde.—(1) The *Pemmatites*, belonging to genus hitherto only known from the Permo-Carboniferous beds of Spitzbergen, was discovered in the Yoredale beds of Yorkshire by Mr. J. Rhodes, and is the only fairly complete sponge which has hitherto been detected in the Yoredale beds of North-west Yorkshire. The author gave a full description of the species. (2) The *Palæacis* was found by the Rev. G. C. H. Pollen in the carboniferous limestone and shale series, on the banks of the Hodder, near Stonyhurst. The specific characters of the form were given by the author, who, in the light of the new information, gave a fresh definition of the genus *Palæacis*, which appears to represent a distinct family of perforate corals, in some features more nearly allied to the Favositidæ than to the Madreporidæ or Poritidæ. (3) The third specimen was discovered by Miss Margery A. Reid in the Lower Carboniferous beds of Halkin Mountain, Flintshire, and is named in honour of its discoverer. A description of it was given, and it was stated that, notwithstanding certain peculiarities, the individual pieces correspond so closely with those of the recent *Eunice* family that it may well be included in the genus *Eunicites*.—The Eocene deposits of Dorset, by Clement Reid. The new survey of the western end of the Hampshire basin shows that the Reading beds become fluviatile and gravelly in Dorset (as was already known), and contain, in addition to chalk flints, many fragments of Greensand chert. The London clay thins greatly and becomes more sandy, but is apparently still marine. The Bagshot sands become coarser and more fluviatile, changing rapidly west of Moreton Station, till they consist mainly of coarse subangular gravel. These gravels, formerly referred to the Reading series, are now shown to be continuous with the Bagshot sands, which as they become coarser cut through the London clay and Reading beds to rest directly on the chalk. The Bagshot gravels contain, besides chalk flints and Greensand chert, fragments of Purbeck marble and numerous Palæozoic grits and other stones probably derived from the Permian breccias of Devon.—Discovery of mammalian remains in the old river-gravels of the Derwent near Derby, Part i., by H. H. Arnold-Bemrose. A few mammalian bones were found in sinking a well at Allenton. On April 8, 1895, the authors commenced further excavations, and were successful in finding a number of bones of a *Hippopotamus*, an *Elephas*, and of a *Rhinoceros*. They were found in a dark-coloured sand above the river-gravel, at a depth of 9 feet 8 inches below the surface. Mr. Clement Reid found some twenty or more species of plant-remains in the sand. These plants "indicate a moist meadow or swampy ground, and a temperate climate. The species are all widely distributed." Part ii., by R. M. Deeley. The deposits in which the bones were found occupy a wide trench which occurs on the inside edge of a gravel-terrace stretching for several miles south of Derby, at a height of 15 or 20 feet above the modern alluvial plain. The gravels are of later age than the great chalky boulder clay, and were formed at a time when the rivers were removing from their preglacial valleys the older boulder clays, with which they had been partially filled. Gravels of two ages are recognised: (*a*) recent gravels well stratified, undisturbed, and covered in many places by a thick layer of brick-earth; and (*b*) high-level gravels showing "trail" and contorted bedding. It is in these latter gravels that the trench containing the mammalian remains occurs.

Zoological Society, May 5.—Dr. John Anderson, F.R.S., Vice-President, in the chair.—Mr. W. E. Hoyle exhibited a Röntgen-ray photograph of a snake in the act of swallowing a mouse.—Mr. G. A. Boulenger, F.R.S., read a paper on some little-known Batrachians from the Caucasus, based chiefly on specimens recently transmitted to the British Museum by Dr. Radde, of Tiflis. Among these was an example of the new frog of the genus *Pelodytes*, for which he had proposed the name *P. caucasicus*. Altogether ten species of Batrachians

were now known from the Caucasus.—Mr. F. E. Beddard, F.R.S., read the second of his contributions to the anatomy of Picarian birds. The present communication related to the pterylosis of the *Capitonidæ*.—Mr. M. F. Woodward read a paper on the dentition of certain Insectivores, and pointed out that there was strong evidence to show that the milk-dentition was undergoing reduction in this group as a whole, some of the milk-teeth in *Erinaceus* and *Gymnura* being present as small calcified tooth-vestiges only, while in *Sorex* there were apparently no calcified milk-teeth, but only vestigial milk-enamel organs.—A communication from Mr. A. D. Bartlett contained some notes on the breeding of the Surinam Toad (*Pipa americana*,) as recently observed in the Society's Gardens. It had been observed that the eggs when issued from the cloaca of the female, which was protruded into a bladder-like process during their production, were arranged on the back of the female by the action of the male.

Anthropological Institute, May 12.—Mr. E. W. Brabrook, President, in the chair.—Mr. H. W. Seton-Karr exhibited and made remarks on a collection of stone implements discovered by him in Somaliland. Sir John Evans, Prof. Rupert Jones, and Mr. C. H. Read spoke and complimented Mr. Seton-Karr upon his discovery.—Dr. J. G. Garson read a paper on recent observations on the Andamanese by Mr. M. V. Portman. A discussion followed, during which remarks were made by Sir William Flower, Prof. Keane, Mr. C. H. Read, and Prof. Brigham of Honolulu. Dr. Garson read another paper on photographic apparatus for travellers, and exhibited a number of cameras of various designs.

EDINBURGH.

Royal Society, May 4.—Prof. M'Kendrick in the chair.—Dr. John Macintyre made a further communication describing new results with the X-rays. Some of these have already appeared in NATURE (vol. liii. p. 614). He found that his coil gave better results when a mercury interrupter was used, and, on regulating this to give one flash in the tube, he was struck by the peculiar colour of the discharge. He exhibited a photo of the hand taken with one flash, which was quite distinct. With ten flashes it was excellent. What the exposure would be in the case of one flash, he could not say. He had tried the effect of the rays on tourmaline, but could find no trace of polarisation. Prof. M'Kendrick said he had satisfied himself that the rays had no effect on the electric phenomena of the pulsating heart, nor on the motor nerves, but that they had an influence on the currents referable to the retina.—Dr. J. C. Dunlop read a paper on the action of acids on the metabolism. He showed them to have a marked diuretic action, to affect the acidity of the urine only slightly, the acidity being to a great extent neutralised by an increased alkali excretion, and to produce an increased excretion of nitrogen as pre-formed ammonia and extractives, but not as urea. His results did not agree with those of Dr. Haig in the same field.—The Secretary read a paper on clouds, by Mr. John Aitken.—Dr. C. G. Knott read a paper by Prof. J. M. Dixon, on a graphical representation of emotion as expressed in rhythm. The author plotted a graph of the number of syllables in each stanza of Browning's "Abt Vogler," and endeavoured to deduce from the graph the variations in Browning's feelings. Other specimens were treated similarly.

PARIS.

Academy of Sciences, May 11.—On the *rôle* of the induction ring of iron in dynamo-electric machines, by M. Marcel-Deprez. A discussion as to the cause of the effect produced by the ring of iron in dynamos of the Pacinotti type. Some experiments are cited which tend to show that the explanations usually given in text-books are insufficient. The complete theory will be given in a future paper.—Nitrates in potable waters, by M. Th. Schlœsing. The results are given of a large number of determinations of nitrates and of calcium in potable waters from various sources. Curves are given showing the variations of these with the season.—On the crepuscular phenomena, and the appearance of the dark face of Venus, by M. Perrotin.—On regular non-linear substitutions, by M. Antoine.—An elementary demonstration of a theorem of M. Picard on complete functions, by M. E. Borel.—Remarks on the preceding communication, by M. Picard.—On the periodic solutions of the problem of the movement of a body suspended by one of its points, by M. G. Kœnigs.—On the rotation of solids and Maxwell's principle, by M. R. Liouville. An examination of a case for which Maxwell's principle does not hold good.—Observations concerning the note of M. Dongier on a method of measuring double refraction, by M. G. Friedel. It is pointed out that the method of M. Dongier was anticipated by the author in 1893.—On the lowering of the explosive dynamic potential by ultra-violet light, and the interpretation of certain experiments of M. Jaumann, by M. R. Swyngedauw. The study of the influence of the rate of variation of potential upon the explosive potential must be made in the absence of ultra-violet light. The neglect of this precaution vitiates the results obtained by M. Jaumann.—On the condensation of dark light, by M. G. Le Bon. Two plates of metal (copper and lead), after exposure to an electric arc for an hour, were made to enclose a negative and a sensitive plate, the faces that had not been exposed to the light being inwards. Precautions were taken to eliminate the possible effects of heat and of contact. That the resulting image must have been caused by something stored on the surface of the metal plates during the exposure to the arc lamp, was definitely proved by the negative results of parallel experiments with plates not exposed to the arc lamp.—The action of hydrogen bromide upon thiophosphoryl chloride, by M. A. Besson (see Notes, p. 63).—The action of air and of peroxide of nitrogen upon some halogen compounds of bismuth, by M. V. Thomas. The halogen compounds studied included the tribromide, triiodide, and the dichloride, which yielded as ultimate products bismuth oxybromide, bismuthic oxide, and bismuth oxychloride respectively.—Action of ethyl-oxalyl chloride upon the aromatic hydrocarbons in presence of aluminium chloride, by M. L. Bouveault. Under suitable conditions this reaction readily results in the production of ethyl phenyl-glyoxylate, or its derivatives.—On a new method of separating the methylamines, by M. Marcel-Delépine. The mixture of amine hydrochlorides is boiled with caustic soda, and the gases passed into commercial formaldehyde. This distillate is now heated with caustic soda, and, after drying, submitted to fractional distillation. Three principal fractions are obtained, at 15°–20°, 67°–68°, and 166° C. The first is trimethylamine, and the two latter, on heating with alcoholic hydrochloric acid, yield the pure hydrochlorides of dimethylamine and methylamine. The separation is more perfect than in the classical method with ethyl oxalate.—On the Synascidia of the genus *Colella*, and the polymorphism of their buds, by M. Maurice Caullery.—On the nephridia of *Branchiobdella varians* (var. *Astaci*), by M. D. N. Voinov.—Formation of an anti-coagulating substance by the liver in presence of peptone, by M. C. Delezenne.—On the effects produced on certain animals by the toxins and anti-toxins of diphtheria and tetanus injected into the rectum, by M. P. Gibier. Toxins and anti-toxins injected *per rectum* are without any effect, and appear to be destroyed or retained by the rectal mucus. For the animals used in the experiments (rabbit, dog, and guinea-pig), the toxins did not poison, and the anti-toxins conferred no immunity.—Hydrographical researches of M. Spindler in Lake Peypous, by M. Venukoff.

PHILADELPHIA.

Academy of Natural Sciences, March 31.—Prof. Henry A. Pilsby called attention to a fine collection of barnacles obtained from the bottom of a vessel recently returned from a voyage to Hong Kong from San Francisco and back, by way of Java and India. *Balanus tintinabulum* was the commonest of the species represented, the varieties *zebra* and *spinosus*, although growing under identical conditions, retained their individuality perfectly.—The question of the constancy of varietal characters was debated by Messrs. Sharp, Pilsby, and Heilprin.—Mr. Pilsby also described a specimen of *Pugnus parvus*, a ringiculate mollusc. The species is involute, a unique character, none of the fossil forms of the family possessing it. He also described a Central American Melanian, under the name *Pachycheilus Dalli*. It is distinguished by a remarkable double sinuation of the outer lip, which has a deep and wide pleurotonoid sinus above, and a rounded projecting lobe in the middle, below which it is again retracted.—On the nomination of the Entomological Section, Dr. Henry Skinner was elected Professor in the Department of Insecta. In response to an invitation from the Committee having charge of the celebration of the fiftieth year of Lord Kelvin's tenure of office as Professor of Natural Philosophy in the University of Glasgow, General Isaac Jones Wistar was appointed to represent the Academy on the occasion.

March 25.—Dr. George H. Horn made a communication regarding the synonymy of the Elateridæ. He specially described the prosternum of Ludius. A Lower California form had the pro-

sternum of different shape from that of other members of the genus, the mesosternum being more protuberant. It will probably be referred to Probothrium.—Mr. Chas. S. Welles exhibited specimens of the larva of *Harrisimemna trisignata*. When full-grown they bore into wood preparatory to changing into chrysalids.—A paper was read entitled "The breeding habits of *Periplaneta orientalis*," by C. Few Seiss. Three females deposited twenty-five egg-cases. Each of these contains sixteen eggs, so that a new generation of 400 cockroaches was represented by the deposit. The first of these egg-cases were dropped May 5 and May 14, 1895, and were hatched November 9. In most cases the deposits were dropped with no attempt at concealment, although in a few instances they were placed in little trenches made by the insect, and then covered up. The development of the capsules was described. The young, probably, receive no maternal care or protection.—Mr. Lancaster Thomas exhibited an improved form of insect net-frame made from a continuous piece of rounded aluminium wire.—Mr. Westcott suggested linoleum as a substitute for cork in the arrangement of insects.—Dr. Henry Skinner called attention to a fungus, *Polyporus betulinus*, which might be used for the same purpose with advantage.—Mr. William J. Fox stated that about ninety species of Hymenoptera, six of which were perhaps new to science, were included in the collections of insects brought by Dr. A. Donaldson Smith from Western Somaliland, Africa.

DIARY OF SOCIETIES.

THE PHOTOGRAPHY OF HISTOLOGICAL EVIDENCE.

An Atlas of the Fertilisation and Karyokinesis of the Ovum. By E. B. Wilson, with the co-operation of E. Leaming. (New York and London: Macmillan, 1895.)

PROF. WILSON has earned the gratitude of teachers and students of biology by publishing his "Atlas of Fertilisation." He has collected, on ten plates of a convenient size, a series of photographs illustrating the development of *Toxopneustes*, from the mature ovarian ovum until the formation of a sixteen-celled blastosphere. The photographs were made by Dr. Leaming, from sections prepared by Prof. Wilson; and they have been admirably printed from untouched negatives. Each figure is about three and a half inches in diameter, so that all details capable of photographic reproduction can be easily seen.

The first plate contains two photographs of ovarian eggs, in which the nuclear structure is well seen; a third, showing the nuclear division leading to the first polar body; and a fourth, showing the mature egg after extrusion of both polar bodies. The next four plates illustrate the entrance of the spermatozoön, the approximation of the male and female nuclei, and the formation of the "asters." The sixth plate shows the changes in the approximated nuclei during the pause which follows the entrance of the spermatozoon; and the seventh, eighth and ninth contain twelve very beautiful figures of the first division of the fertilised egg. Finally, some of the later divisions are exhibited on the tenth plate.

The photographs are accompanied by a short but clear account of the phenomena they are intended to illustrate; and in many cases difficult details are rendered intelligible by means of diagrams.

There can be no doubt that this Atlas will be of great service to students and to teachers, as an exposition of our present knowledge concerning the main facts of fertilisation; although one is tempted to regret the absence of any figures demonstrating the number of chromosomes, either in the polar bodies or the pronuclei. The excellence of the work suggests, however, another standard by which to judge it—a standard indicated by Prof. Wilson himself in his preface, when he points out that the most careful drawings involve a subjective element from which photographs are free, and states his belief that, in spite of certain necessary shortcomings, "the photographic plates here presented give, on the whole, a clear and accurate impression of the preparations."

If photography could indeed provide an image of histological preparations, as clear and accurate as that received by the eye of a trained observer, then a great step would have been made; for every histologist would be enabled to convey to others the whole evidence for his statements in a way before impossible; and a photograph, when once successfully taken, might serve as material for future research in the hands of men unable to procure the object photographed.

Unfortunately, Dr. Leaming's photographs, admirable as they are, do not approach the perfection necessary if they are to be regarded as representing the whole evidence given by the actual sections. This may easily be seen by any one who tries to determine from them the truth of some statements made in the text.

Prof. Wilson holds the view, now shared by the majority of observers, that both the centrospheres of the fertilised egg arise from a portion of the spermatozoon; and he considers that the male and female chromatin elements lie side by side, without mixing, during the division of the single original centrosphere. As evidence of this, he gives photographs 17, 18 and 19, and woodcuts xi. and xii. In the woodcuts, the distinction between the male nucleus and the female is clear and unmistakable; while, at least in photographs 18 and 19, this is not the case. Again, in the photograph fig. 19 there is no clear indication of structure in the male nucleus; while in the woodcut fig. xii. B, which may well have been drawn from the actual section photographed, a distinct reticulum is indicated in its substance.

Few persons will believe that Prof. Wilson has made positive statements on the evidence of sections showing no more than the photographs referred to: every one will feel that the woodcuts represent the essentials of his preparations better than the photographs. So that we have to judge the question, after all, by reading the author's account of what he says he saw; and when photography has done its best, the evidence of the condition of these nuclei at a particular moment still rests upon his reputation as a histologist, as completely as it would have done had he published the woodcuts only, or no figures at all.

In the case just referred to, the author's statement is so completely in accord with those of other workers, that few will hesitate to accept it; but when he points to photograph No. 19 as evidence that the rays of the amphi-aster "are really fibres, and not, as some recent authors have maintained, merely the optical sections of thin plates or lamellæ in a radially arranged alveolar structure," there is equally little evidence one way or the other to be obtained from the photograph, while there is more room for doubt as to the accuracy of the interpretation. The reference is, of course, to Bütschli's work on the structure of protoplasm; and those readers of NATURE who have compared Prof. Bütschli's photographs with his drawings, will remember that in his case also the photographic reproduction of the evidence was not a material addition to the strength of the argument.

On the whole, it seems certain that the best photograph at present possible does not show so much as can be seen by looking directly at a good histological preparation: so that it is not yet possible for a histologist to multiply copies of his evidence in a form from which the subjective element is altogether excluded. There is still no way of testing a histological statement without direct examination of the object described. Further, it seems that a careful drawing by a trained observer gives a better idea of appearances seen under the microscope than the best available reproduction by photography can at present achieve.

W. F. R. WELDON.

THE KEW INDEX OF PLANT NAMES.

Index Kewensis Plantarum Phanerogamarum. Sumptibus beati Caroli Roberti Darwin ductu et consilio Josephi D. Hooker confecit B. Daydon Jackson. Fasciculus iv. Pp. 641–1297. (Oxonii: e prelo Clarendoniano, 1895.)

THE serial issue from the press of large works of reference like that under notice does not always proceed with the rapidity which, to those whose appetites are whetted by foretaste, appears possible and desirable. It is therefore with all the more satisfaction that we chronicle the issue with commendable promptness of this, the fourth, fasciculus of the Kew Index, by which the work is brought to completion. Botanists and all who have concern in the names of plants are thereby furnished with a book which must always form an essential tool in their library equipment.

The appearance of the earlier fasciculi gave occasion for a notice in NATURE of the aim and scope of the work, and it is not necessary therefore to refer to these again, the less so as the two years that have elapsed since the first fasciculus came into our hands have sufficed to familiarise those who have need to use such a book with its value as a standard work of reference. It may not, however, be mistimed to repeat here the caution given by the Director of Kew in his address at the Ipswich meeting of the British Association, that the work is no more than its name signifies. It is a sound and safe guide; it is not a critical botanical work. The bulk of the names as cited in the Index may be regarded as definitely fixed for the nomenclature of botanists, at least in Great Britain; but throughout the volumes any one may find abundant evidence that it was not the intention of those who have laboured to produce this magnificent work to go beyond the identifications established in the literature of botany at the date at which their citations close. Further study and investigation must result in modifications of limits imposed by the state of botany in 1885, and names will change therewith; but such alterations of names, the acceptation or rejection of which must be a matter of botanical opinion, will not detract from, but will rather enhance the value of the Index as a standard of botanical nomenclature.

In no direction is the beneficent influence of the publication of the Index more immediately to be looked for than in the literature of horticulture, and it is in this aspect that the book will appeal to that large section of the public delighting in gardening, and which naturally objects to purchasing from a nurseryman the same plant over and over again under different names. It would appear that the Index is already exercising an effect, and that nurserymen are disposed to use the botanical name, if not instead of, at least cited alongside of, the trade name for plants in their catalogues—a practical result for which we cannot be too thankful, and in the hastening of which we must recognise the stimulus given by the excellent series of hand-lists of plants cultivated in the Royal Gardens, Kew, now in course of publication.

On the completion of their labours upon this vast work the botanical world will accord to Mr. Daydon Jackson and Sir Joseph Hooker its hearty congratulations, nor will it forget that to Mr Darwin it owes the projection and endowment of the book. To the Clarendon Press, too, its thanks will be given for the dress in which it has sent out the volumes. Whatever may be the future of botanical nomenclature—and the opening of the twentieth century is threatened with no less an infliction than a new "nomenclator," prepared in conformity with his own special principles by Dr. Otto Kuntze, which is to sweep away the nomenclature of the Kew, Berlin, and New York "cliques" (the productive seats of systematic botany)—botanists in all time must recognise the sound, judicious, conscientious workmanship displayed in the Index Kewensis through which it takes and will retain its value as a work of reference.

THE ANATOMY OF FEAR.

Fear. By Angelo Mosso. Translated from the fifth edition of the Italian, by E. Lough and F. Kiesow 8vo. Pp. 277. (London, New York, and Bombay: Longmans, Green, and Co., 1896.)

THE learned and eloquent Professor of Physiology at Turin has given us in the book which he has entitled "Fear," an analysis of this mental condition and its accompanying physical states, which, marked as it is by scientific accuracy and couched in charming and even in poetical diction, will take high rank as a popular exposition of our knowledge of the expression of one of the most interesting of the emotions of both men and animals. The extent of ground which is covered by the author, and the amount of information which he has contrived to convey within a small compass, excites our astonishment and admiration. Nor, in spite of the complicated scientific problems which are dealt with, is there a word of heavy reading from beginning to end. The book is beyond measure interesting, and one that when taken up it is difficult to lay down unread. Clearly it was impossible in a work with this title to avoid gruesome details, and readers whose nerves are disagreeably affected by descriptions of morbid conditions may put the book down with a shudder when they arrive at a passage in which a pathological case, which is used to illustrate the argument, is painted in glowing language from the life. For the author has in no wise burked such details; on the contrary, they come before one from time to time in the work with a vividness which transports one bodily to the hospital ward, the asylum, the vivisection table! But there is at the same time such a strong under-current of sympathy with suffering pervading the whole, that while the reader will come away from the scenes depicted, deeply interested in the lessons which they teach, there is no fear that he will be rendered callous by the familiarity which he has acquired with their horrors.

The idea of the book is to endeavour to rest the expression of this important emotion upon a physiological basis. With this aim in view, the effects of dread upon the heart and circulation, upon the respirations, upon the muscular system both voluntary and visceral, upon the secretions, and upon the central nervous system, are portrayed. Nor does the author confine himself strictly to the emotion which gives the book its

title, although this naturally constitutes the main theme. The number of other subjects incidentally treated of, furnishes a pleasing variety, and largely helps to maintain the interest of the reader, whether he be scientific or not. In pursuing his subject, Prof. Mosso is led into a criticism of Greek art, and contrasts as a medium of expression of the emotions the works of Phidias and Praxiteles with those of the schools of Pergamos and Rhodes. He compares the Niobe with the Laocoon; in the former he finds lacking "the expression of intense emotion, of horror, fear, and pain, which would inevitably be present in the terrible moment of so cruel a butchery."

"Though Praxiteles himself were the creator of the Niobean group, I yet hold that a humble physiologist, looking with dispassionate eye at these statues, may affirm that they fall short of the fame of so great a master, because the faces are not so modelled as to produce the desired effect, because nature is not faithfully copied, and because there lacks the sublime ideality of terror aroused by the chastisement of an offended deity, which was the subject of the work."

On the other hand, in spite of certain anatomica errors in the furrows of the brow in the Laocoon,

"an intense and majestic pain is written on the face, . . . one seems to hear the sigh of superhumân agony from his lips, and sees the lines of beauty and of pain wonderfully blended."

In touching upon questions of inheritance, the author shows himself rather a disciple of Spencer than of Darwin. But it is not clear upon what evidence he founds the statement that if two hounds of the same litter are taken, and one trained for sport and the other as a watch-dog, their offspring, after four or five generations of such training, although brought up under the same conditions and far from noise, will be in the one case excited, in the other terrified on first hearing the report of a gun. Nor I conceive will the assertion be generally accepted that the disappearance of the eyes in subterranean animals "is certainly not the result of natural selection, for eyes are not injurious even to beings living in the dark." On the other hand all will agree with the author in deprecating the installation of fear in the child, of which the ignorant mother or nurse is so often guilty.

"The children of ancient Greece and Rome used to be frightened with the lamias who would suck their blood, with the masks of the atellans, the Cyclops, or with a black Mercury who would come to carry them away. And this most pernicious error in education has not yet disappeared, for children are still frightened with the bogey-man, with stories of imaginary monsters, the ogre, the hobgoblin, the wizard and the witches."

"Children should be brought up as though they were rational. . . . The same methods should be followed in education as in the teaching of science . . . we should never issue any command without showing the reasons why it should be done in this way rather than in another." . . . "They must not be fatigued with study . . . even for healthy children premature education is a very grievous error."

"Parents who have already some weak spot—a little fault in the character, a slight blemish in the organism—should redouble their care in order to cure their children from their own defects. . . . The paramount object of education should be to increase the strength of man, and to foster in him everything which conduces to life. . . . We sometimes imagine that the most important branch of culture is that which we attain through education and study . . . but in ourselves, our blood, there is a no less important factor. . . . Fear is a disease to be cured; the brave man may fail sometimes, but the coward fails always."

The translation is excellent throughout.

E. A. SCHÄFER.

OUR BOOK SHELF.

Die Physiologie des Geruchs. (*The Physiology of Smell.*) By Dr. H. Zwaardemaker. Pp. 324. (Leipzig: Engelmann, 1895.)

VON HARTMAN, in defending himself against a friend who upbraids him for having wasted upon philosophy talents which might have been devoted to the accumulation of facts of positive science, points out in memorable words that facts of science are amassed only in order that they may be synthesised.

The critic is bound to remember this in appraising a book like that of Dr. Zwaardemaker's, for Dr. Zwaardemaker has added to the burden of physiological facts, and he has not established any generalisations to assist us in the carrying of that load.

If we overlook this fact, and we ought not to overlook it lightly, the work is a most praiseworthy one, a work that is characterised by the thoroughness which the Teuton strives after, and which, as a matter of fact, is found in the best of Low German science. There are very careful chapters in this book, only to mention a few, on the physical characteristics of odorous substances, on the mechanics of smell, on "olfactory" and "breath-fields," on the relations between taste and smell, on a new method of testing the acuity of smell, on the masking of smells by other smells, on the classification of smells, and on Prof. Haycraft's work on the relations between odour and chemical composition. Many of these subjects are treated with considerable originality. The "breath-field" is mapped out by breathing on a bright metallic surface. It is shown that two patches of dimness are produced, corresponding respectively to the right and the left nostril. It is further shown that each of these fields is subdivided into two smaller fields by a linear interspace, which in all probability corresponds to the inferior turbinated bone. The two patches of dimness on each side, therefore, in all probability correspond to the two streams of air which pass respectively above and below the lower turbinated bone. The patch of dimness which corresponds to the current of air which passes over the lower turbinated bone is conterminous with the olfactory field as determined by an independent method.

The apparatus for testing the acuity of smell consists of a porous clay cylinder, which is fitted up somewhat after the manner of a syringe. The piston-rod consists of a tube which serves to convey the air into the nostril. The air which is thus fed into the nostril consists in part of inodorous air which has been drawn in from without through the open end of the clay cylinder, and in part of air which has been in contact with the walls of the porous cylinder which has been impregnated with an odorous substance. The proportion of odorous to inodorous air can be varied at pleasure by regulating the position of the piston in the cylinder.

The chapter on the association between smell and taste emphasises the fact that there is an inlet to the olfactory chamber through the posterior nares, as well as through the nostrils. We therefore smell both when we inspire and when we expire. It is because he is ignorant of this fact that the layman is incredulous when he is

informed that many of the sensations which he refers to taste are in reality referable to smell, and it is on account of the same ignorance, that the child thinks he is treated irrationally when his nose is held while his castor-oil is being administered to him.

A few facts of this sort will be all that an ordinary reader will carry away from a perusal of this book. The book will be really valuable only to the physiologist who, like Dr. Zwaardemaker, is willing to devote himself to the study of the physiology of smell.

Computation Rules and Logarithms. By Prof. Silas W. Holman. Pp. xlv + 73. (New York and London: Macmillan and Co., 1896.)

THE first portion of this book treats of the way to use logarithms so as to apply no more figures than necessary; the author pointing out that probably one half of the time expended in computations is wasted through the use of excessive number of places of figures, and through the failure to employ logarithms. With this in view, rules are given showing what place tables to employ, and also how many figures to retain to obtain an accuracy of any desired percentage.

That such rules are of high importance may be seen from the fact that the use of five place tables when four would suffice nearly doubles the labour; using six place instead of four nearly trebles it, thus wasting a hundred and two hundred per cent. respectively of the necessary amount of work, and probably a greater proportion of time.

Besides these rules and the usual explanation to the collection of mathematical tables, there is a short treatment on "Notation by Powers of Ten," which, as the author sees, is a method that if taught with elementary arithmetic, it would enormously facilitate the teaching of logarithms; but his "Symmetrical Grouping of Figures" about the unit's place is a departure likely to be received with some degree of conservatism. There is a useful paragraph on the "Habit in Reading off Numbers or Logarithms," which consists in emphasising and grouping the figures in a certain habitual way. The latter part of the book is taken up by a collection of mathematical tables, *e.g.* logarithms, antilogarithms and cologarithms to four places, logarithms to five places, logarithms of the trigonometrical functions, slide wire ratios to four places, &c. The decimal point, usually omitted, has been retained in the tables for facilitating in reading off.

Remarkable Eclipses. By W. T. Lynn. Pp. 52. (London: Edward Stanford, 1896.)

THIS "sketch of the most interesting circumstances connected with the observation of solar and lunar eclipses, both in ancient and modern time," appears at a very appropriate time, since in a little more than two months the general public will be mildly interested in a total eclipse of the sun, for the observation of which in Norway, Japan, and elsewhere, many astronomers are making preparations. Mr. Lynn has contrived to compress a marvellous amount of very readable information in his slender little volume, and as a condensed statement of the history of eclipse observations his essay is admirable. The book is uniform with "Remarkable Comets," and it deserves the same successful career as its forerunner.

The Old Light and the New. By Wm. Ackroyd, F.I.C. Pp. 102. Illustrated. (London: Chapman and Hall, Ltd., 1896.)

WE very much question the wisdom of placing this book upon the market. The information on researches with Röntgen rays is very sketchy, while a large portion of the book, dealing with theories of the natural colours of bodies, is nothing more than padding, and is altogether out of place in a volume of this character.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Curious Idiosyncrasy.

A STRONGLY marked idiosyncrasy has lately come to my notice, which should be recorded. A lady of my acquaintance was walking with a relative, Colonel M., when the wife of a tenant addressed her, and described how the hand of her own child had been pinched in a door. Overhearing her story, Colonel M. became quite unwell, so much so as to lead to particular inquiry, which resulted in showing that allusions to any accidents of that kind affected him at once in a very perceptible way. Finally, at the request of the lady, he wrote an account of his peculiarity, which she forwarded to me. Thereupon I corresponded with Colonel M., who slightly revised what he had written, and sanctioned its publication. It is as follows:—

"From my earliest remembrance, and still up to now, any sight of an injured nail in any person, even if a total stranger, or any injury, however slight, to one of my own nails, causes me to break into a deadly cold perspiration, with feeling of sick faintness. But still further; if I chance to hear any one else narrating in casual conversation any injury of this particular sort to themselves or others, it brings on me exactly the same feeling I have described above. So much is this the case, that many years ago, when I was in the prime of life, at a large dinner party, when one of the guests near me persistently chanced to go on talking minutely of some such little accidental injury that had befallen him, I turned very faint, tried all I knew to shake it off, but could not, and presently slid right under the table quite unconscious for the moment. This is the more singular because on no other point am I in the least squeamish. In old days I have seen soldiers flogged before breakfast without its affecting me, though some of the rank and file would be very much upset, and in cases of death, illness, or wounds, I have never experienced, as an onlooker, the sensations I have alluded to above."

I may mention that the mother of Colonel M. had pinched her own finger-nail badly shortly before his birth, and, as is not uncommon in coincidences of that kind, she believed her accident to have been the cause of her son's peculiarity. He writes to me:—

"As a boy I was conscious of this repugnance of mine, but was ashamed of it, and never used to mention it to any one. When I became a young man I one day mentioned it *privately* to my mother, who it appeared had already noticed it in me as a child. She then told me the incident about her own finger, and she and I being both utterly unscientific persons, assumed then and there that my squeamish feelings about injuries to finger-tips must be connected with her little accident."

In reply to further questions, I learn that the injury to the mother, however painful at the time, was not so severe as to leave a permanent mark. Also, that no analogous peculiarity is known to exist among the near relations of Colonel M., of whom he specifies his father, brother, three sisters, nephews and nieces. He has no children.

This anecdote proves, so far as the evidence goes, that a very peculiar idiosyncrasy may spring suddenly into full existence, and need not develop gradually through small ancestral variations in the same direction. It is a more astonishing phenomenon than the equally sudden appearance of musical faculty in a single member of a non-musical family, being very special, and so uncommon and worse than useless that its ascription to reversion, in the common sense of the word, would be absurd. That is to say, it would be silly to suppose a sickly horror of wounded finger-nails or claws to have been so advantageous to ancient man or to his brute progenitors, as to have formerly become a racial characteristic through natural selection, and though it fell into disuse under changed conditions and apparently disappeared, it was not utterly lost, the present case showing a sudden reversion to ancestral traits. Such an argument would be nonsense. But though this particular characteristic is of negative utility, its existence is a fresh evidence of the enormously wide range of possibilities in the further evolution of human faculty.

FRANCIS GALTON.

Becquerel's and Lippmann's Colour Photographs.

The point raised by Prof. Meldola (p. 28) is partially, if not completely, answered by Otto Wiener in a most valuable paper, "Ueber Farbenphotographie durch Körperfarben, und Mechanische Farbenanpassung in der Natur," published in *Wiedemann's Annalen*, 1895, lv. 225–281. Wiener devised a method of examining colour photographs through a right-angled prism in such a way that pigment colours, which owe their hues to absorption, are distinguished from interference colours by not changing their positions when seen through the prism. The application of this method to colour photographs by Lippmann's process and the older processes of Seebeck, Poitevin and Becquerel, shows that in Lippmann's photographs the colours are due entirely to interference. In Becquerel's process they are due mainly to interference, though pigment colours are formed to an extent which is generally very small, but which increases with the duration of the exposure. The colours on Becquerel plates *do* change with the angle of incidence, though the changes are very small, probably in consequence of the high refractive power of the film. Further, when the film is examined from the back the colours do not occupy the same positions as when they are viewed from the front. It follows that the colours on Becquerel plates are due essentially to the same cause as those on Lippmann's plates, and the theory of standing waves is applicable in both cases.

With the processes of Seebeck and of Poitevin, on the other hand, the colours are exclusively pigment colours, and the theory of standing waves is not applicable.

Weston-super-Mare, May 16. C. H. Bothamley.

Influence of Terrestrial Disturbances on the Growth of Trees.

In reply to the note of Mr. H. J. Colbourn on "Influences of Terrestrial Disturbances on the Growth of Trees," in your issue of April 23, allow me to say that his ingenious suggestion of connecting a zone of narrow rings in a section of Douglas spruce with some supposed terrestrial disturbances occurring about the same time, is hardly tenable, even if the coincidence of the two phenomena were established, which seems not to be the case. The occurrence of a zone of narrow rings is common in all our trees, and I have observed it most frequently in all southern pitch pines, which are rarely over three hundred years old, and hence outside of the possibilities of the influence of unknown or uncertain terrestrial disturbances.

The suddenness with which the rings become narrow and then again wide, described by Mr. Colbourn, and observed by us in many other trees, is, to be sure, puzzling; nevertheless, we cannot escape the conclusion that it is due to changes in the conditions surrounding the tree. Yet it is not necessary that the change of conditions and of ring-width should be simultaneous, that is to say, the change of conditions may have occurred without having been immediately responded to by the growth of the tree.

The following explanation may serve as a type. Let a tree grow up under favourable conditions for a hundred years, as the Douglas spruce in question seems to have done, when its ring-growth will be wide, its crown reaching above its neighbours. A hurricane breaks off a large part of its crown, when necessarily and suddenly, at least within a year, the rings become narrow in proportion. Within the next thirty years the crown recuperates, which in a resinous conifer like the Douglas spruce is possible without fear of fungus attacks and decay; but the food-material descending from the foliage will for a long time be only sufficient, on the particular section in question at the base of the tree, to make the narrow annual ring, even after the crown is fully recuperated. Were a section cut higher up in the tree, it would be found that the rings there have begun to widen sooner than at the lower section. Finally, and rather suddenly for any given section, the supply has become normal, and especially if an exceedingly favourable season occurs at the same time the rings show again normal width.

The same sudden change from narrow to wide rings is observed when a tree oppressed by its neighbours is suddenly relieved by windfall or by man's interference from its oppressors; but the response even then is not simultaneous, it takes one or more years before the crown is in condition to utilise the full amount of light at its disposal, and to furnish food to all parts of the tree in increased ratio. B. E. Fernow.

Washington, D.C., May 11.

Our Bishops and Science.

The friends of both science and religion will thank you warmly for publishing the Bishop of Ripon's public testimony to Huxley's spirit of sincerity and love of truth. It is the more timely because of your recent strictures upon the Bishop of London. May I therefore, as a country parson, with an equal love for scientific integrity and religious truth, suggest to the readers of those strictures in Nature (p. 607, April 30) that probably Bishop Temple has been misunderstood. I am sure it is not fair to his spirit to put into his mouth, "Away with all these abominations. Purge the elementary schools of everything scientific, and substitute dogmas and subjects more fitted to the stations of life in which it has pleased God to call the scholars."

Is it not more likely that the real clue is in the sentence quoted about "instructing little children in *elementary* schools in *a great many scientific subjects?*" For many earnest educationalists have, as friends of science, spoken strongly on the evils of the cramming of bits of science subjects and "stages" by crudely crammed "Government certificated" "science" teachers cramming large classes for grants on "passes" to butter their bread.

In any case, the true views of the great bishop will be found in his "Bampton Lectures" for 1884, on the relations between science and religion; and the last *Quarterly Review*, on G. J. Romanes, contains an eminent example of the reverent treatment of both.

I will frankly add that I do not think your quotations from Mr. Mundella's address can be too widely known among the bishops and clergy who have such influence with the laity. Agricultural pursuits suffer more from our ignorance than our want of money; and agricultural science cannot be widely taught until the elementary principles of chemistry and physics are diffused in our villages.

On this subject we have also had the weighty testimony of Mr. Gladstone. The voting of money for light railways and such objects is a quack remedy. The fact is that true educational enthusiasts who will think first of our children, and be generous to them *first*, have hitherto been appallingly scarce in the House of Commons and its parties.

Nor is even the *geographical* significance of our need of science education likely to be perceived by the majority, if, as is stated in the *Anti-Slavery Reporter* (March–April 1896, p. 80), two M.P.s can stand before a map of South America in the map room of the House of Commons, and dispute with one another as to where Egypt was to be found on that map. However matters are mending, we hope. J. F. Heyes.

Crowell, Oxon, May 15.

Blood-Brotherhood.

There are good reasons why this ancient custom can never be a preventive of disease, though sometimes it may be a cause of it. The serum treatment has been found useful, and presumably will be found useful only in such diseases or diseased conditions as are due to poisons (toxins) secreted by various species of pathogenic micro-organisms (*e.g.* those of rabies, anthrax, diphtheria), or by some animals (*e.g.* scorpion, snake), as weapons of offence or defence.

As regards certain zymotic diseases (*e.g.* small-pox, scarlatina, syphilis), it is known that one attack confers more or less complete immunity against subsequent attacks; that is, the micro-organisms of these diseases are, after the recovery of the host, unable to persist and produce their toxins in him; and this for the reason that during his illness certain of his body cells, known as phagocytes, become inured to the toxins, and are thus enabled to attack and destroy the micro-organisms producing them. When the phagocytes fail to become inured, the micro-organisms continue to produce these toxins, and the host perishes, poisoned by them. Now the toxins produced by the micro-organisms of most zymotic diseases are not always of the same degree of virulence, and when they are feeble the phagocytes the more easily become inured to them, and destroy the micro-organisms; and not only do they do so, but this preliminary training enables them, when attacked by more virulent micro-organisms of the same species, *i.e.* of the same disease, to react to the stronger toxins of these also, and again destroy the micro-organisms. Man has taken advantage of this fact to artificially lower or "attenuate" the virulence of various species of pathogenic micro-organisms (*e.g.* those of anthrax an

cholera); and inoculation with them or their toxins inures the individual so treated to resist the attacks of micro-organisms of the same species and of the normal degree of virulence. One way of attenuating or rendering less virulent the toxins is to inject them into an animal that does not easily perish of them (*e.g.* horse, as regards diphtheria), when they undergo partial intracellular digestion within his tissues. His blood serum then contains altered toxins (the so-called anti-toxins), experience of which inures the cells of an animal of a more susceptible species (*e.g.* man) to resist the attack of virulent micro-organisms with unaltered toxins. It is noteworthy that when toxins and anti-toxins are mixed the latter may inure the cells to the former before death occurs, for the reason that these do not under normal conditions cause immediate death. For this reason animals are able to withstand much more than a fatal dose of a toxin when it is mixed with the appropriate anti-toxin, and sometimes even to recover from a disease which would otherwise be fatal if during the course of it the anti-toxin is injected. But toxins and anti-toxins are not retained within the system. They are digested by the cells and excreted, and therefore enduring immunity is not conferred by their presence, but by the fact (in some diseases at least) that when the cells are once inured they remain so.

It is clear that the serum treatment can be useful only in diseases against which immunity may be acquired, if only for a short time. In other diseases (*e.g.* tuberculosis, malaria, leprosy) against which immunity cannot be acquired, which do not run a pretty definite course of limited duration, of which one attack does not protect against subsequent attacks, it is useless; for here training does not benefit the cells, or if in some cases it does benefit them, this benefit is of such limited duration as to be practically useless.

After this, from want of space, very dogmatic statement of the rationale of serum-therapeutics, let us inquire what may be hoped from the ceremony of blood-brotherhood in its medical aspects. Clearly nothing. It will not, of course, endow the traveller with his blood-brother's powers of resisting hardship (heat, cold, hunger, &c.); it will not confer immunity or increased powers of resistance against that class (the most death-dealing class) of diseases against which immunity *cannot* be acquired; and lastly, it will not confer immunity or increased powers of resistance against that class of diseases against which immunity *can* be acquired, unless there is present in the blood-brother this or that micro-organism in an attenuated form, or unless antitoxins are present in him to an inconceivable degree of concentration—very remote possibilities, or rather impossibilities, on which the traveller were wise not to count. On the other hand the blood-brother may communicate actual virulent disease, for instance syphilis and malaria.

G. ARCHDALL REID.

Remarkable Sounds.

IN a Japanese work, "Hokuetsu Kidan," by Tachibana no Mochiyo (published *circa* 1800, tom. ii., fol. 5, *seqq.*), I have found some remarkable sounds described. Among the details given therein of the "Seven Marvels of the Province of Echigo," we read: "The fifth marvel, the Dônari [literally *Body Sounds*, or *Temple Sounds*], is a noise certain to be heard in the autumnal days, just before a fine weather turns to stormy, it being sounded as if the thunder falls from the cloud, or the snow slides down a mountain. Where it originates is quite uncertain, as there are in the counties several mountains assigned therefor. The sounds are heard of same intensity in variously distant places." Further, the author recites a folk-tale current in his time among the villagers of Kurotori, in Co. Kambara, which attributes these sounds to the head and body of a hero, Kurotori Hyôe [killed in 1062?]; separately interred under a Shintoist temple in this village, they ever strive to unite once more. "The marvel, it is said, is now seldom met with; still it occurs frequently within two or three miles of the village, proceeding doubtless from the precinct of the temple. And the fact is more wonderful that the inhabitants of Kurotori themselves never hear the sounds unless they go out of the village." Concluding the narrative, the author, from his personal observation, argues the action of the tide-waves upon the earth to be the real cause of these curious sounds.

May 18. KUMAGUSU MINAKATA.

BOSNIA-HERZEGOVINA AND DALMATIA.

THE progress of prehistoric archæology, the youngest of the inductive sciences, is one of the more important facts in the history of the intellectual development of the latter half of the nineteenth century. Up to 1870, attention was chiefly directed to the antiquity of man and his place in the geological record, and to the classification of his advance in the Neolithic, Bronze, and Iron ages in Europe. Man was proved to have lived in a remote past, not to be measured by years and under climatal and geographical conditions totally different to those now met with in Europe. The next ten years were chiefly spent in elaborating the details as to the range of Palæolithic man, and in working out the sequence of events, separating the Pleistocene period from the dawn of history. The Neolithic, Bronze, and Prehistoric Iron ages of human progress were traced far and wide over nearly the whole of the old and the greater part of the new worlds. In the last decade the centre of archæological interest has shifted slowly in the direction of the frontier of history. On the one hand the researches of Flinders Petrie have revealed the close connection of ancient Egypt with the nations of the Mediterranean long before the rise of the Greeks, and have rendered it possible for us to use the Egyptian chronology as the standard to fix the date of prehistoric events in Southern Europe and in Asia Minor. On the other, in these latter areas, many workers, among whom Schliemann stands foremost, have revealed the manners and customs, the daily life, the modes of warfare, the habitations, fortresses and tombs of the very peoples who were in touch with Egypt. We even know, thanks to Arthur Evans, that there was a system of writing in the Ægean area long before the introduction of the Phœnician alphabet, and we may look forward to his future researches to make it intelligible.

A valuable book[1] on Bosnia-Herzegovina and Dalmatia is the last contribution to the subject. Under the modest title of "Rambles and Studies," it might very well be taken for the usual book of travels in a land of wonderful beauty, till now practically closed to the ordinary traveller. Under the Austro-Hungarian dominion, now some twenty years old, good roads have replaced the old tracks, and law and order reign instead of the brigandage of the past. New lines of railway and of steamers connect the chief centres, manufactures are encouraged, and schools for the education of both Christian and Moslem are in full swing. There are luxurious hotels in place of the old caravanserais, and the records of the past are being carefully preserved in museums, under the charge of competent scientific men, instead of being ruthlessly destroyed, as they were under the old *régime*. There are snow-covered mountains, great rivers and waterfalls, like those at Ottawa, and lakes embosomed in trees. There are ravines, like those of Miller's Dale, only larger, and caverns, and all the characteristic scenery of the limestone forms the surface of the country. The interest, however, chiefly centres in the inhabitants. The present phase of transition from Eastern to Western ideas is of special value at this time, when the cry of oppressed lands is ringing in the ears of the Western nations, because it shows with what extraordinary rapidity a people ground down to the dust for centuries by the Turk, may become happy and prosperous under a good system of local self-government. What the Austro-Hungarians have done in the Bosnia-Herzegovina, may be done by the Powers in Asia Minor and in the islands of the Ægean Sea. From this point of view Dr. Munro's well-written book is worthy of the attention of our rulers. Dr. Munro has dealt with all these things with a light and pleasant

[1] "Rambles and Studies in Bosnia-Herzegovina and Dalmatia." By Robert Munro, M.A., M.D., F.R.S.E. 8vo. (Blackwood, 1895.)

hand. He, accompanied by Mrs. Munro, travelled under great advantages. He went in 1894, at the invitation of the Austro-Hungarian Government, to attend an archæological congress, and he has made the most of his opportunities.

It is not, however, the traveller's side of the book which more immediately concerns us. It is rather with it as a contribution to archæological literature, in which the author brings to bear, on the discoveries made in those lands by others, the scientific method which he had already used so well in carrying out his investigations into Lake-dwellings in Britain and on the continent. We shall review in their chronological order the more important of the discoveries, now laid before English readers, in a quarter of Europe shut off by lofty mountain ranges from the pathways of the nations.

The group of Neolithic remains at Butmir gave rise to much difference of opinion at the congress. According to Mr. Radimsky, they were deposits of refuse round ancient huts on the land, and the irregular amœba-like hollows in the clay were taken to be the bases of huts. In Dr. Munro's opinion these hollows were made by the extraction of the clay for the covering of the wattles of the huts, as well as for the large amount of pottery and terra-cotta found on the site. He points out that they have been filled up by the deposit of silt under water, as well as by human débris, and concludes that the whole accumulation was formed in and round pile-dwellings like those of Switzerland, the piles of which, as well as all the other woodwork, have wholly rotted away. We agree with this view; and would advance a further argument in its favour, that a settlement on a clay soil liable to floods is unknown in the history of Neolithic dwellings. On that spot pile-dwellings would be the only habitations possible. The inhabitants were skilful potters, and their vessels made by hand were in some cases ornamented by spirals. They also manufactured stone implements, polished axes, spears, arrows, and the like. They were also spinners and weavers; they had herds of pigs, domestic oxen, among which we may note the short-horned ox (*Bos longifrons*), and flocks of sheep and goats. In their fields they grew wheat and barley, and carried on a trade by barter with other communities. The rude terra-cotta idols imply that they had some kind of religion. Their burial-places have not yet been discovered. Among the purely Neolithic remains are twenty-seven perforated axe-hammers of a type found in the Bronze age elsewhere, and made of a stone which does not exist in the district. With the exception of three, all the rest of the implements amounting to 5118, are of native stone. It is probable that in this out-of-the-way place the Neolithic civilisation lingered long after the Bronze age had begun in the more accessible surrounding districts. We may accept Dr. Munro's conclusion, that the settlement of Butmir "is one of the side eddies of the early stream of immigrants who found their way into Europe by the Danubian valley from the regions to the south and east of the Black Sea," in the Neolithic age, and who lived on into the Bronze age—an age which in Bosnia is not so well defined and conspicuous as it is in Germany, Scandinavia, and Western Europe generally.

While bronze implements and weapons were gradually finding their way into Bosnia-Herzegovina, a new civilisation appeared at the head of the Adriatic, and extended over the southern watershed of the Danube, Northern Italy, the Tyrol and the adjacent regions, known, from the principal site of the discoveries, as that of Hallstadt. From this centre the characteristic products were scattered far and wide over Europe by means of commerce, marking the close of the Bronze and the beginning of the Iron age. The tumuli on the plateau of Glasinac, more than 20,000 in number, mark this age in Bosnia. Of these about one thousand have been explored, proving that both inhumation and cremation were practised. The articles buried with the dead consist of iron knives swords, spear-heads and axes, some double-edged, others in the shape of socketed celts. Bronze vessels, pendants, bracelets, finger-rings, and brooches, were discovered in great variety. The brooches are of great interest as indices to the age of the tumuli. This is marked by the stage presented in the evolution of the brooch from a straight pin. The first stage is presented by the bending of the pin; the second, by its being twisted round so that the point is brought to rest on a development of the head specially made to receive it; the third, by the development of one or more twists, so as to form an elastic spring or springs—the safety-pin type. From those of one spring, the Greek and Roman fibulæ are descended. At Glasinac about 44 per cent. were those with two springs, or of the Hallstadt type. Those with one are more closely allied to the Greek, while others are purely Roman. A helmet from a tumulus at Arareva is of pure Greek type and similar to one found at Olympia, bearing an inscription that it was dedicated by the Argives to Zeus out of the spoils of Corinth. It is also identical with the helmet on a warrior carved on the Harpy Tomb, Xanthos, Lycia, in the British Museum. Both these belong to about the middle of the sixth century before Christ. These things were found along with an infinite variety of ornaments and implements of bronze, iron and silver, of glass and amber and bone, together with fragments of pottery. It is obvious that these tumuli were used from the remote Hallstadt time down to the days of the Roman dominion. It is not a little remarkable that there is no mention of coins in the three elaborate volumes recording these discoveries, published by the scientific staff of the Public Museum in Sarajevo. Coins had not then found their way into the country, or if they had, were not buried with the dead.

In 1890 a cemetery was discovered at Jezerine, belonging to the same period as the tumuli of Glasinac, and containing the same types, but with fewer weapons. It is remarkable for the beautiful rings and beads made of blue, yellow, white and green glass. A gravestone with a figure of a warrior found here is assigned by Dr. Hoernes to the late Hallstadt period. The helmet with the lofty crest reaching far down the back is identical with that carved on the Harpy Tomb at Xanthos, and those on the heads of warriors, on painted early Greek vases. It may very well be of late Hallstadt age, as well as early Greek.

Besides burial-places such as the above, there are numerous forts belonging to this people, similar in construction to the hill-forts of Scotland, and built of rubble masonry without mortar.

Nor are we without evidence as to the physique of the people themselves. Of thirty-two human skulls from Glasinac, examined by Dr. Glück, 76 per cent. are either long or mesocephalic, while 24 per cent. are short; a fact of considerable interest when contrasted with the present roundness of head of the Bosnians. Out of 1500 natives examined by Dr. Weissbach, 7 per cent. only were long and 93 per cent. short.

The prehistoric inhabitants of Bosnia, like those of Hallstadt, were mainly long-headed, while the presence of the short-headed minority shows the existence of two races in both regions. The reversal of this in Bosnia in later times is due to the immigration of short-headed people, mostly Slavs, from the time of the tumuli down to the present day. It may be inferred that in Herzegovina and Bosnia, as in Western Europe, the aboriginal and Neolithic peoples were long-headed, and that they were invaded by a new race of round-headed conquerors. Whether this took place in the Bronze age must be left for future inquiry, and whether it took place from the line of the valley of the Danube, or, as Dr. Munro suggests, by the head of the Adriatic, must also be left an

open question in the present condition of the inquiry. The close connection with Hallstadt renders the latter view the more probable, although there is clear proof of the Greek influence from the south. This, however, it must be admitted, may belong to a later period.

In closing this review, we may congratulate Dr. Munro on his success in writing a book which is short, picturesque, and scientific; and we feel sure that he will gain his end, of attracting attention to the archæological treasures awaiting the explorer in this hitherto little-explored corner of Europe. W. Boyd Dawkins.

EXPERIMENTS IN MECHANICAL FLIGHT.

I HAVE been for some years engaged in investigations connected with aerodromic problems, and particularly with the theoretical conditions of mechanical flight. A portion of these have been published by me under the titles "Experiments in Aerodynamics" and "The Internal Work of the Wind," but I have not hitherto at any time described any actual trials in artificial flight.

With regard to the latter, I have desired to experiment until I reached a solution of the mechanical difficulties of the problem, which consist, it must be understood, not only in sustaining a heavy body in the air by mechanical means (although this difficulty is alone great), but also in the automatic direction of it in a horizontal and rectilinear course. These difficulties have so delayed the work, that in view of the demands upon my time, which render it uncertain how far I can personally conduct these experiments to the complete conclusion I seek, I have been led to authorise some account of the degree of success which has actually been attained, more particularly at the kind request of my friend Mr. Alexander Graham Bell, who has shown me a letter which he will communicate to you. In acceding to his wish, and while I do not at present desire to enter into details, let me add that the aerodrome, or "flying-machine" in question, is built chiefly of steel, and that it is not supported by any gas, or by any means but by its steam-engine. This is of between one and two horse-power, and it weighs, including fire-grate, boilers, and every moving part, less than seven pounds. This engine is employed in turning aerial propellers which move the aerodrome forward, so that it is sustained by the reaction of the air under its supporting surfaces.

I should, in further explanation of what Mr. Bell has said, add that owing to the small scale of construction, no means have been provided for condensing the steam after it has passed through the engine, and that owing to the consequent waste of water, the aerodrome has no means of sustaining itself in the air for more than a very short time—a difficulty which does not present itself in a larger construction where the water can be condensed and used over again. The flights described, therefore, were necessarily brief. S. P. Langley.

Through the courtesy of Mr. S. P. Langley, Secretary of the Smithsonian Institution, I have had on various occasions the privilege of witnessing his experiments with aerodromes, and especially the remarkable success attained by him in experiments made on the Potomac River on Wednesday, May 6, which led me to urge him to make public some of these results.

I had the pleasure of witnessing the successful flight of some of these aerodromes more than a year ago, but Prof. Langley's reluctance to make the results public at that time prevented me from asking him, as I have done since, to let me give an account of what I saw.

On the date named, two ascensions were made by the aerodrome, or so-called "flying machine," which I will not describe here further than to say that it appeared to me to be built almost entirely of metal, and driven by a steam-engine which I have understood was carrying fuel and a water supply for a very brief period, and which was of extraordinary lightness.

The absolute weight of the aerodrome, including that of the engine and all appurtenances, was, as I was told, about 25 pounds, and the distance, from tip to tip, of the supporting surfaces was, as I observed, about 12 or 14 feet.

The method of propulsion was by aerial screw propellers, and there was no gas or other aid for lifting it in the air except its own internal energy.

On the occasion referred to, the aerodrome, at a given signal, started from a platform about 20 feet above the water, and rose at first directly in the face of the wind, moving at all times with remarkable steadiness, and subsequently swinging around in large curves of, perhaps, a hundred yards in diameter, and continually ascending until its steam was exhausted, when, at a lapse of about a minute and a half, and at a height which I judged to be between 80 and 100 feet in the air, the wheels ceased turning, and the machine, deprived of the aid of its propellers, to my surprise did not fall, but settled down so softly and gently that it touched the water without the least shock, and was in fact immediately ready for another trial.

In the second trial, which followed directly, it repeated in nearly every respect the actions of the first, except that the direction of its course was different. It ascended again in the face of the wind, afterwards moving steadily and continually in large curves accompanied with a rising motion and a lateral advance. Its motion was, in fact, so steady that I think a glass of water on its surface would have remained unspilled. When the steam gave out again, it repeated for a second time the experience of the first trial when the steam had ceased, and settled gently and easily down. What height it reached at this trial I cannot say, as I was not so favourably placed as in the first; but I had occasion to notice that this time its course took it over a wooded promontory, and I was relieved of some apprehension in seeing that it was already so high as to pass the tree-tops by twenty or thirty feet. It reached the water one minute and thirty-one seconds from the time it started, at a measured distance of over 900 feet from the point at which it rose.

This, however, was by no means the length of its flight. I estimated from the diameter of the curve described, from the number of turns of the propellers as given by the automatic counter, after due allowance for slip, and from other measures, that the actual length of flight on each occasion was slightly over 3000 feet. It is at least safe to say that each exceeded half an English mile.

From the time and distance it will be noticed that the velocity was between twenty and twenty-five miles an hour, in a course which was constantly taking it "up hill." I may add that on a previous occasion I have seen a far higher velocity attained by the same aerodrome when its course was horizontal.

I have no desire to enter into detail further than I have done, but I cannot but add that it seems to me that no one who was present on this interesting occasion could have failed to recognise that the practicability of mechanical flight had been demonstrated.

Alexander Graham Bell.

THE APPROACHING CELEBRATION OF THE KELVIN JUBILEE IN GLASGOW.

IT may interest our readers to state the programme of the approaching celebration of the jubilee of Lord Kelvin as Professor of Natural Philosophy in the University of Glasgow.

On the evening of Monday, June 15, at 8.30 p.m., the University will give a conversazione, when there will be an

exhibit of Lord Kelvin's inventions. On Tuesday, June 16, addresses will be presented to Lord Kelvin by delegates from home and foreign University bodies, from several of the learned Societies of which he is a member, from student delegates from other Universities, and from the students and graduates of the University of Glasgow. It is expected that the honorary degree of LL.D. will be conferred on the same day on several of the distinguished foreign visitors. On Tuesday evening, June 16, the City will give a banquet to Lord Kelvin, to which the visitors who have come to do him honour have been invited.

On Wednesday, June 17, the Senate of the University will invite the visitors of the University staff to sail down the Clyde. The students of the University also invite the students' delegates from other Universities to a similar trip.

Representative scientific men—about fifty in number—from America and the British colonies, and from all the European countries, and about 150 from the United Kingdom, have signified their intention to be present.

The exceptional nature of the occasion, and the feeling which Lord Kelvin's name awakens everywhere, will give these proceedings a peculiar interest.

NOTES.

THE University of Wales is to be represented at the forthcoming celebration of the Kelvin jubilee by Principal J. Viriamu Jones, F.R.S., of Cardiff (the Vice-Chancellor for the year), and Prof. A. Gray, of Bangor.

THE Mayor of Bristol, at the suggestion of a deputation representing the chief local scientific societies and educational institutions, has decided to invite the British Association to visit Bristol in 1898. A visit to Bristol after the Toronto meeting would be made in a singularly opportune year, for it was in 1497 that Cabot discovered the American mainland, where the Association will be in 1897, whence he started on his second voyage in 1498. The meeting would thus serve to commemorate the tercentenary of a memorable voyage of one of Bristol's greatest citizens. That the Association should take Bristol after Canada would, therefore, be very appropriate.

THE Epidemiological Society of London has resolved, having regard to the historical connection of the Society with vaccination and other preventive measures, to found a medal in memory of Jenner. It is proposed that the medal shall be founded with a view to the promotion of epidemiological research, and that it shall be bestowed from time to time by this Society on persons who shall have contributed to the knowledge of preventive medicine. Donations (not exceeding one guinea) may be sent to the Honorary Treasurer, 6 Hereford Mansions, Bayswater, W.

THE death is announced of Dr. August Hosius, Professor of Mineralogy and Palæontology in Münster University.

THE King of Belgium has honoured Prof. Leo Errera, Professor of Botany in the Université Libre de Bruxelles, and Director of the Institut botanique, by creating him a Chevalier of the Order of Léopold.

REUTER'S correspondent at Adelaide states that a well-equipped expedition started on May 22 to explore the interior of the Australian continent. It will be absent eighteen months. Mr. Calvert is defraying the cost of the expedition.

AN extra Friday evening meeting of the members of the Royal Institution will be held on June 19, when Mr. Thomas C. Martin, of New York, American Delegate to the Kelvin jubilee, will deliver a lecture on "The Utilisation of Niagara."

WE learn from the *American Naturalist* that a biological station will be opened on June 22 at Biscayne Bay, Florida, and will remain open for six weeks. The place is well situated for the study of the tropical and subtropical flora and fauna, while its situation upon the continent makes it more readily accessible than the West India Islands. The station will be under the direction of Prof. Charles L. Edwards, of the University of Cincinnati.

MR. T. D. A. COCKERELL proposes to establish a biological station at Las Cruces, New Mexico, U.S.A. The climate of the country is exceptionally favourable for persons in the earlier stages of phthisis, while the abundance of new and interesting forms of life, especially among the insects, is remarkable. Many interesting general problems, such as those of the life-zones, can also be studied in New Mexico to great advantage. A beginning will be made this summer if students can be found. Mr. Cockerell will be glad to hear from any who are interested in the matter, and especially from those who might be inclined to work with him for longer or shorter periods during the present summer.

A GENERAL meeting of the members of the Federated Institution of Mining Engineers will be held in London on Thursday, June 4, and on Friday, June 5. The following papers will be read, or taken as read:—Presidential address, by Mr. Geo. A. Mitchell; "The Causes of Death in Colliery Explosions," by Dr. J. S. Haldane; "Road Engines," by Mr. John McLaren; "The Gobert Freezing Process of Shaft-sinking," by Mr. A. Gobert; "Precautions necessary in the Use of Electricity in Coal-mines," by Mr. H. W. Ravenshaw. The papers down for discussion are: "Photography in the Technology of Explosives," by Mr. Alfred Siersch; "Coal-washing Plant at the Wirral Colliery, Neston, Cheshire," by Mr. J. Platt; "Lead and Lap of Winding and other Engines," by Mr. Hargrave Walters.

THE gold medal of the Linnean Society of London, which is annually presented alternately to a zoologist and to a botanist, has this year been awarded to Prof. George James Allman, F.R.S., for distinguished researches in zoology. A graduate in medicine in the University of Dublin in 1844, and subsequently Regius Professor of Botany there, he was elected a Fellow of the Royal Society in 1854, and from 1855 to 1870 held the chair of Regius Professor of Natural History in the University of Edinburgh, where the honorary degree of LL.D. was conferred upon him. In 1873 he was awarded the "Royal Medal" of the Royal Society. In 1874 he was elected President of the Linnean Society in succession to Mr. Bentham, and in 1879 was President of the British Association on the occasion of its meeting at Sheffield. His chief scientific work has relation to the lower forms of animal life, concerning which his most notable publications are his monographs of the Freshwater Polyzoa and Hydroida—issued by the Ray Society—and his exhaustive report on the Hydroida collected by the *Challenger* exploring expedition. The medal will be presented at the anniversary meeting of the Linnean Society, to be held on Thursday, June 4, at 8 p.m.

MESSRS. C. GRIFFIN AND CO. have just published the thirteenth annual issue of their "Year-Book of Scientific and Learned Societies of Great Britain and Ireland." The work comprises lists of papers read during 1895 before these societies, which are arranged into fourteen classes according to the branches of science fostered by them. As a handy and accurate index to our scientific societies, and a record of progress, the work is most useful.

WE learn from *La Nature* of May 23 that a meeting was held on April 24, at the Geological and Geographical Society of Stockholm, in favour of the Polar expedition of M. Andrée. That gentleman opened the meeting by an explanation of the preparations already made, and of the prospects of the expedition. The generator of the hydrogen gas is nearly

completed, and the steamer *La Vierge* is in dock at Gothenburg. A folding canvas boat, to carry three persons and 600 kilograms of provisions, has also been constructed. The expedition is to sail from Gothenburg on June 7, and should arrive at Spitzbergen about the 18th of that month. After that, M. Andrée cannot state what may happen—whether it will be a long balloon voyage, or a sledge and boat journey. M. Ekholm enumerated the various instruments which will be taken; they include several self-recording meteorological instruments, photographic apparatus, and electrometer. M. Strindberg gave details respecting the construction of the balloon. After the meeting a banquet took place, at which Baron Nordenskiold wished success to the expedition, to which M. Andrée warmly responded.

In spite of the numerous excursions that have been previously made to Spitzbergen, it is remarkable that so very little has been done in the interior. The botany of its coast-lands is as well known as that of many British counties; its mosses, hepatics, and marine algæ have been carefully monographed. Many groups of the fauna have been equally well described. The geology of the coast sections has been mapped, and rich collections of fossils made from the remarkably rich sequence of rocks ranging from the Devonian to the Pleistocene, and including representatives of the Carboniferous, Permian, Trias, Jurassic, Cretaceous and Miocene. Nevertheless hardly anything is known of the interior of West Spitzbergen, the largest island of the archipelago. Nordenskiöld and Palander crossed the north-east island in June 1873, but up to the present only two short excursions have been made on to the ice-sheet of the main island. The first of these was a short traverse by the late Gustav Nordenskiöld from Horn Sound to Bel Sound, and the other a visit by Ribot to Mount Milne-Edwards, to the south-east of Ice Fiord. The interior is known to be covered by an ice-sheet, and a careful study of this would no doubt throw much light on the problems of the former glaciation of Europe. An effort to fill this remarkable gap in our knowledge is now being made by Sir W. Martin Conway, who has organised an expedition to Spitzbergen, which will start on June 2. The main object of the expedition is the study of the interior, but it is hoped also to supplement our knowledge of the fauna of the coast-lands, and to make extensive collections for this country. The party will consist of five other members, Mr. Ed. Conway, Mr. R. D. Darbishire, Mr. E. J. Garwood, Dr. J. W. Gregory, and Mr. A. Trevor-Battye. The party expects to return early in September. The collections made will be the property of the British Museum, the Trustees of that institution having lent Dr. Gregory's services to the expedition.

Writing to the *Electrician* on the subject of Röntgen rays, Mr. James Mark Barr enunciates the proposition that reversing the current in a "focusing" tube improves it for its normal working after "fatiguing" has set in. He adds that the reverse current used should be comparatively weak.

A fine specimen of a rare Marine Chalonian, the Leathery Turtle (*Dermochelys coriacea*) has lately been presented to the South African Museum by Mr. P. C. Keytel, of Cape Town. The animal was stranded on Blaauwberg beach in Table Bay, and was secured by some fishermen; its length is over 5 feet, and its breadth more than 2 feet.

In the *Indian Engineer* some interesting statistics are given relating to the development of the coal fields in Labuan. The island contains four seams of coal varying in thickness from 1½ to 10 feet, and running from north-east to south-west. The coal is good steam coal containing an abundance of resin, and the outcrops are three-quarters of a mile from the sea. In prospecting for coal near the head of the Ogangara River, oil was struck, which continued to flow for a few days, when the spring became exhausted. The yearly output of coal three years ago was 18,000 tons.

The current number of the *Journal of the College of Science*, at Tōkyō, fully maintains the standard of its predecessors; but we note with deep regret the announcement of the death of Mr. Hirota, whose last paper (on the "Dendritic Appendage of the Urogenital Papilla of a Siluroid") it contains. The half-dozen monographs which have fallen from Mr. Hirota's pen are of exceptional merit, and show their author to have been a worker of much promise and sound judgment. His first paper on the "Sero-Amniotic Connection and the Fœtal Membranes in the Chick" came as a revelation; and let it be recorded to his lasting memory, that he therein disposed of an error in fundamentals, of which Western embryologists, studying the hen's egg *ad nauseum*, had never dreamt. We tender our Eastern confrères our profoundest sympathy, for their loss is our own.

A protest is raised in the *Agricultural Gazette of New South Wales* (vol. vii. part 2) against the indiscriminate destruction of beneficent lady-birds. The small yellow and black-banded pumpkin beetle, *Aulocophora hilaris*, Boisd., feeds upon many plants frequented by the 28-spotted lady-bird, *Epilachna 28-punctata*, and it is common to find these two destructive species side by side upon the same plant. This appears to have led to the misapplication of the term "lady-bird" to *Aulocophora hilaris*, with the unfortunate result that the whole of the group Coccinellidæ, to which the appellation properly belongs, has been, in the most general terms, denounced and described as a scourge. Considering that, out of the large number of species of lady-birds to be found in New South Wales, only two—*Epilachna 28-punctata* and *Epilachna guttato-pustulata*—are really injurious, it would be a great misfortune if all the useful species of Coccinellidæ were to be ostracised on their account.

The last number of the American journal, *Modern Medicine and Bacteriological Review*, draws attention to a report recently drawn up by Prof. Conn, of the Western University, on the bacteriology of milk, published by the United States Department of Agriculture. Examinations of milk made at various places yielded numbers varying from 330,000 to 9,000,000 microbes per ounce. The milk-supply of Boston was found to be particularly rich in microbes, as many as 135 million germs being found per ounce. The *Boston Medical and Surgical Journal* lately reported a case in which a young man contracted tubercular disease by drinking milk from a herd of cows, fifty-nine of which were afterwards found to be tuberculous, whilst two persons employed in making butter from the same herd, and who drank large quantities of milk, also became infected. Although much has been accomplished in our country of late years to improve the sanitary conditions surrounding our public milk-supplies, yet a great deal still remains to be done, and there cannot be a doubt that the next important step will be the distribution by our dairies of "pasteurised" milk and butter. The example has already been set by one important London dairy company, and it is to be hoped that others will follow what is, after all, but a tardy imitation of what has been done for some time past by our more enlightened neighbours on the continent.

In commemoration of the Jenner centenary, a special number of the *British Medical Journal* has been issued, containing a number of interesting papers on Edward Jenner's life, work, and writings.

The Clarendon Press announces for early publication a "Flora of Berkshire," by Mr. G. C. Druce. It is intended to be not only a catalogue, but also a history, of the plants of the county.

DR. PH. MOLLE has reprinted from the *Memoirs* of the Royal Academy of Belgium his "Recherches de microchimie comparée sur la localisation des alcaloïdes dans les Solanacées." These alkaloids are found chiefly in the superficial organs of the plant, especially in the bark, where they serve to protect it against the attacks of herbivorous animals. They are entirely absent from both the embryo and the endosperm of the ripe seeds, and can in no sense be regarded as reserve food-materials; if they occur at all in the seed, it is only in its integument.

MR. C. F. CLARKE, of Plumstead, writes to point out a clerical slip in the notice of Dr. Orchard's "Astronomy in Milton's Paradise Lost," by which Satan's shield is said to be compared to Galileo's glass (not a very large object, that of the Lick or Yerkes telescope might have been more appropriate had such then existed), instead of the moon as viewed through it. Besides the three constellations mentioned in our notice, Milton also alludes to Orion, supposed by him, as by the ancient poets, to be associated with windy and stormy weather.

WE welcome No. 12 of the *Alembic Club Reprints*, published by Messrs. W. F. Clay, Edinburgh. The volume contains Faraday's papers on "The Liquefaction of Gases" (1823-1845), and an appendix consisting of papers by Thomas Northmore on the compression of gases, which were referred to by Faraday, in his historical statement, in the following terms. "The most remarkable and direct experiments I have yet met with in the course of my search after such as were connected with the condensation of gases into liquids, are a series made by Mr. Northmore in the years 1805-6." Students of physics, and every one interested in the subject of the liquefaction of gas, should possess a copy of this latest addition to the *Alembic Club Reprints*.

THE Deutsche Seewarte has recently issued tbe last of its series of atlases dealing with maritime meteorology and other useful information relating to the great oceans. The present work, which refers to the Pacific Ocean, contains thirty-one folio coloured charts, with explanatory text, and, like its predecessors, forms an appendix to the Sailing Directions which are published in a separate form. The atlases for the Atlantic and Indian Oceans have been in the hands of German sailors for some years, and, being in a clear and popular form, are almost equally useful to other countries. In addition to the usual charts of ocean currents, specific gravity, temperature of air and sea-surface, relative frequency of winds, distribution of rainfall, &c., there are others containing useful *data*, among which we may mention the mean sailing routes, and the distribution and principal haunts of various kinds of whales. The charts are based on a large amount of information supplied by German captains, and include materials collected by other nations. A just appreciation of this part of the work of the Deutsche Seewarte is shown by the fact that it has been found necessary to prepare a second edition of the Sailing Directions for the Atlantic Ocean, which will be published as soon as practicable.

THE *Journal* of the Asiatic Society of Bengal can scarcely be said to have a place in our chemical libraries; the current number, however, contains a paper by Dr. P. C. Rây, of the Presidency College, Calcutta, on mercurous nitrite, that is worthy of note. During a preparation of mercurous nitrate by the action of dilute nitric acid in the cold on mercury, yellow crystals were deposited which, upon examination, proved to be mercurous nitrite. The analysis proved somewhat difficult, as the substance dissociates in solution into metallic mercury and mercuric nitrite. The fact that this nitrite is stable in strongly acid solutions, is an additional proof of the views advanced by Dr. Divers as to the "nitronic" constitution of the nitrites of copper, silver, mercury, and bismuth. The stability of silver nitrite towards nitric acid has already been noticed by Acworth and Armstrong, and by Russell, and the behaviour of mercurous nitrite is closely analogous. Dr. Râv proposes, in a subsequent communication, to give the results of an attempt to prepare fatty nitro-derivatives from this compound.

THE Commissioners of the St. George's Public Library record in their second report, that good progress has been made with the arrangement of the cases and specimens comprised in the natural history collection presented to the library. The donor generously undertook the laborious task of installing, classifying, and labelling the whole of the objects, as well as the preparation of the numerous explanatory reading-cases, which will contribute so much to the proper understanding of the contents of the room. The collection may now be considered as ready for the use of students, and it affords an illustration of what can be done to connect the public libraries with natural history museums generally. Certain annual subscriptions were promised for three consecutive years towards the cost of maintaining the collection, but unfortunately in the second year (1895) the full amount has not been realised. It is stated that at least £150 is required to cover the working expenses during the four years for which the Commissioners have undertaken to house the collection, until it shall be seen whether good use is made of it by natural history students; the cost of *installation* having been defrayed partly out of the library rate and partly by the donor.

THE School of Practical Science at Toronto may be proud of an Engineering Society which can issue a volume of *Proceedings* (No. 9) such as we have just received. The papers in the volume are of more than engineering interest. Mr. McLennan has a paper on "Röntgen Radiation," detailing results obtained by him; and special attention should be called to an excellent essay on "The Pendulum," by Mr. A. M. Scott, which gained for the author the 1851 Exhibition Science Scholarship allocated by the University of Toronto. There is also an original contribution on the action of heat upon cements, and another on brickwork masonry. Even astronomy finds a place in the volume. Mr. W. L. Innes contributes a brief history of celestial science, and Mr. A. T. Laing describes an ingenious planetarium devised by him. As an instance of the value of a little astronomical knowledge, we may refer to a short paper on "Aspect and Prospect," by Mr. C. H. C. Wright, in which a diagram is given to show the azimuth of the sun at any time of the year for any place in the latitude of Toronto. The diagram, which is due to Prof. Kerr, should be of much assistance to architects in deciding upon the best aspects for windows of various rooms. Other subjects treated are lightning arresters, planimeters, standards in machine shop practice, the Chicago Canal, and a simple form of telemeter.

THE Report of the American Museum of Natural History, just issued, shows notable increase in the various collections, and large and expensive additions to the building. The expeditions to Peru, Honduras, Sumatra and Mexico, have resulted in the acquisition of a large number of interesting objects and photographs. In the department of Public Instruction, regular courses of lectures have been delivered to the teachers of the public schools, and free lectures to the people on public holidays as well as every week. The department of Mammalogy and Ornithology received in 1895 the William Dutcher Collection of New York Birds, numbering over two thousand specimens, contributed by the Linnean Society of New York. A very large number of Arctic mammals and birds have been received as the result of the expedition to Greenland. The department of Vertebrate Palæontology has been enriched by the Cope Collection of Fossil Mammals of North America, comprising nearly ten thousand specimens, representing 483 species. The acquisition of this valuable collection establishes the Museum as a

centre of study and research in palæontology. Increasing interest in the Museum has been evinced by all classes of the citizens of New York. Every course of lectures has been attended by crowded audiences, and pupils of public and private schools, as well as students of science, have derived advantage from the library as well as from the collections.

Several new editions of scientific works have reached us during the past few days. The first volume of a new edition of Prof. Fleming's systematic treatise on "The Alternate Current Transformer," dealing with the induction of electric currents, has been published by the *Electrician* Printing and Publishing Co. The great progress made during the seven years which have elapsed since the appearance of the original work, has necessitated a thorough revision of the matter, and the volume as it stands now will be appreciated by all who are concerned with alternating-current practice or investigations. Another volume having practical electricity for its subject is "Electric Lighting and Power Distribution" (Whittaker and Co.), by W. Perren Maycock. The first volume of the third edition of this work has been issued in an enlarged form, after careful revision. The second edition of the first volume of Dr. Schlich's "Manual of Forestry" has been published by Messrs. Bradbury, Agnew, and Co. The original was reviewed in Nature in December 1889 (vol. xli. p. 121), and quite recently (April 2, p. 510) was referred to in these columns. The second edition contains a new part on the State in relation to forestry, and a general review of the timber requirements of the British Empire. Messrs. Longmans, Green, and Co. have issued a second edition of "The Essentials of Chemical Physiology," by Dr. W. D. Halliburton. The chief alterations made are those rendered necessary by the advance of knowledge since 1893, when the first edition was published. The fifth edition of "Southall's Organic Materia Medica," by J. Barclay, has been published by Messrs. J. and A. Churchill. To quote the sub-title, the volume is "a handbook treating of some of the more important of the animal and vegetable drugs made use of in medicine, including the whole of those contained in the British Pharmacopœia." New editions of two volumes by the late Dr. J. E. Taylor, have been received from Messrs. W. H. Allen and Co. The books are "Nature's Byepaths," a series of recreative papers in natural history, and "The Aquarium," a popular manual on the history, construction, and principles of management of public aquaria. Dr. G. Herbert Fowler has edited the sixth edition of the late Prof. Milne Marshall's valuable work on the anatomy, histology, and dembryology of "The Frog" (David Nutt). A few additions and alterations have been made, but the work remains substantially the same practical and educational handbook that it ever was. Finally, the recent changes in the Physiography Syllabus of the Department of Science and Art have resulted in the production of a new edition (the sixth) of "Earth Knowledge" (Part II.) by W. Jerome Harrison and H. R. Wakefield. The book follows the Department's Advanced Syllabus, and appears to fulfil the purpose for which it has been designed.

The additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Sir William Call; a Blue-bearded Jay (*Cyanocorax cyanopogan*) from Para, presented by Mr. H. C. T. Beadnell; four Puff Adders (*Vipera arietans*), two Ringhals Snakes (*Sepedon hæmachates*), an Egyptian Cobra (*Naia haje*), three Cape Vipers (*Causus rhombeatus*), a Cape Bucephalus (*Bucephalus capensis*), two Infernal Snakes (*Boodon infernalis*), a Nilotic Monitor (*Varanus niloticus*) from South Africa, presented by Mr. J. E. Matcham; a Grey Ichneumon (*Herpestes griseus*) from India, deposited; two Indian Tree Ducks (*Dendrocygna javanica*) from India, purchased; a Japanese Deer (*Cervus sika*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Temperature Errors in Meridian Observations.—M. Hamy has applied his method of interference fringes to a study of the errors caused in meridian observations by the radiations of the sources of light usually employed in observatories, as well as those due to the presence of the observer himself (*Bull. Ast.*, vol. xiii. p. 178). The researches have completely demonstrated that the unequal distribution of light sources may produce errors in the measures amounting to several seconds of arc, while the heat from the observer may affect the results to the extent of several tenths of a second. It is evident therefore that the subject is one of great importance, and the interferential method is specially adapted for its investigation. M. Hamy has arrived at his conclusions from experiments made with the Gambey meridian circle of the Paris Observatory. In the case of an ordinary gas flame at a distance of 0·83 metre from the telescope, the mean angular displacement of the optic axis with respect to the meridian amounted to 2″·1, the flame being lit for ten minutes. Other observations indicate that the deviation is sensibly in inverse proportion to the square of the distance of the flame from the optic axis. The effects of different sources of light were also compared at one metre distance, and the practical outcome is that gas flames provided with chimneys are to be studiously avoided, the variation in collimation amounting in this case to 4″·4. The errors due to the heat of the human body are greatest in the case of declination measures, owing to the greater heating of the under side of the telescope tube. It is evident that these errors will depend to some extent upon the materials of which the instrument is constructed, and M. Hamy is of opinion that the best possible material is a metal of high conductivity, such as copper, in which case inequalities of temperature would be almost impossible.

Search Ephemeris for Comet 1889 V.—The following is a continuation of Dr. Bauschinger's search ephemeris for the return of Brooks's periodic comet (1889 V) (*Ast. Nach.*, No. 3350).

	R.A. h. m. s.	Decl. ° ′	Brightness.
May 28	22 2 38	−19 44	0·44
June 1	7 17	19 29	0·48
5	11 43	19 14	0·52
9	15 54	19 1	0·56
13	19 49	18 49	0·61
17	23 26	18 39	0·66
21	26 44	18 30	0·71
25	22 29 44	−18 22	0·77

The unit of theoretical brightness is that on 1889 July 8, the date of the first accurate observation. The comet was last seen in January 1891, at the Lick Observatory, when the calculated brightness was only 0·08. During June the computed path lies in the southern part of Aquarius, so that observations can only be made in the early morning.

Constants for Nautical Almanacs.—At a convention of Directors of Nautical Almanacs, held at Paris after the recent congress of the International Photographic Chart, Dr. Gill's value of the solar parallax (8″·80), resulting from heliometer observations of minor planets, was adopted, and consequently the constant of aberration becomes 20″·47. Dr. Gill's value for the mass of the moon, leading to 6″·21 for the nutation, was also adopted, and Newcomb's value was accepted for the precession.

The Planet Mercury.—A postcard from Dr. Kreutz, Kiel, contains the information that Mr. Leo Brenner, of the Manora Observatory, saw the dark part of the planet Mercury sharp and distinct on May 18, at 23h. Manora time.

STELLAR PHOTOGRAPHY WITH SMALL TELESCOPES WITHOUT DRIVING-CLOCKS.

Stellar photography has now become such an important branch of astronomy, that anything which will encourage possessors of small telescopes to turn their energies in this direction will tend towards the advancement of the celestial sciences. It is proposed to show here that useful work may be done by amateur astronomers with their ordinary small refractors, and with none of the mechanical contrivances which are essential for such large telescopes as are used in the international photographic survey of the heavens, which are driven by elaborate and

costly machinery in order that the camera shall follow the apparent motion of the stars.

The accompanying photographs were taken with a 3½-inch refracting telescope of 29 inches focus, totally unprovided with any driving mechanism, not even a tangent screw and slow-motion rod, the guiding having been performed entirely by hand. The correct rate of angular motion was secured by constant visual observation of the image of a star, much out of focus, as seen in a 2½-inch guiding telescope, carrying an eyepiece magnifying fifty times. This was mounted side by side with the telescopic camera, and moved with it.

Fig. 1 shows the instruments mounted on a firm equatorial stand which is supported on a home-made brick pillar. The 2½-inch guiding telescope, by Cooke of York, is seen on the left, provided with its total reflection prism and eyepiece, and just above it is a small "finder." On the extreme left is a counterpoise which balances the 3½-inch photographic telescope, which is on the opposite side of the declination axis, and is mounted in a home-made wooden tube of square section, with dew-cap and diaphragms of the same material. At the lower end the dark slide is seen, and behind is a smaller camera which carries an ordinary portrait lens of 2½-inch aperture, which is used for obtaining a duplicate photograph, on a smaller scale, simultaneously with the larger one. The whole is so evenly balanced by the two

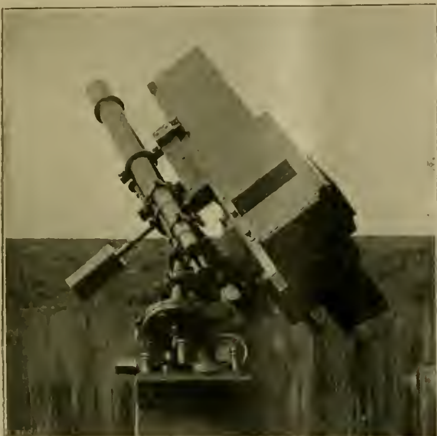

FIG. 1.—3½ inch Equatorial Photographic Telescope (as used for hand driving).

counterpoise weights—one of which is seen low down on the right—that when unclamped it remains at rest in any position. Adjusting screws are provided in order to move the telescopic camera slightly in right ascension or declination whilst the guiding telescope remains stationary. This enables one to use the nearest bright star for guiding purposes when the centre of the photographic field contains no conspicuous stars. Absolute parallelism of the two telescopes is of no importance, but their rate of angular motion must be identical. Interesting results can be obtained with such a telescopic camera without any guiding whatever. The camera remaining fixed, the images of the stars travel along on the plate and leave "trails," which appear on the negative as straight or curved parallel dark lines.

By placing a small ink dot at one end of each of these lines, the relative positions of the stars can be indicated. It was found that the faintest stars visible to the naked eye, leave trails on negatives taken with such a 3½-inch camera, and accurate charts of stars down to the sixth magnitude can be very easily secured in this manner.

These trails can also be usefully employed in certain cases to secure records of the changes of brightness of "variable" stars, as faint stars give very fine lines, and brighter stars leave thicker and denser ones on the negatives. Variations in brightness are thus recorded in the varying thickness and density of the lines, which are compared with the trails of other standard stars near. From what has been said about trails, and seeing that the image of a star moves more than its own diameter on a stationary plate in a few seconds, it is evident that all the naked-eye stars can be photographed with such an instrument with an exposure of a few seconds. As an illustration of this, a photograph taken with an exposure of only fifteen seconds, when the crescent moon was

FIG. 2.—Orion's belt. (Exposure 30 min.)

close to the Pleiades, showed not only the crescent, but also the "old moon in the new moon's arms," due to earth-shine, and twelve of the stars in the Pleiades. Accurate hand driving for such a short period is a matter of comparative ease.

Fig. 2 shows a photograph of Orion's belt taken with an exposure of thirty minutes. The negative on close examination shows stars down to the tenth magnitude. In the region represented,

FIG. 3.—The Pleiades. (Exposure 60 min.)

only about eight stars can usually be seen with the naked eye. The photograph shows that amateurs can obtain, by half an hour's exposure, a chart of any region of the sky, much more accurate and revealing a far larger number of stars than are shown in the star atlases usually in their hands. These photographs, obtained by such simple means, can always be used as records, and might easily serve for the detection of "new" and "variable" stars

when repeated at intervals and compared. The scale of these photographs is 3·4 times as large as that of Klein's Star Atlas, and the area of any region is 11·5 times larger. This is somewhat smaller than Argelander's charts.

The multiple star δ Orionis, a single star to the naked eye, is well shown as three stars, one of which is much elongated, showing the duplicity of that component; a curious S-shaped group of stars is clearly seen between δ and ε. These are quite invisible to the naked eye.

Fig. 3 represents the Pleiades as photographed with sixty minutes' exposure. In the region shown, ordinary keen eyes see only seven stars. On the negative seventy-eight stars can be counted in a space of 3° square in the centre of this region. These include stars of the eleventh magnitude.

As regards the actual driving of the telescopes, very little practice is needed; a gentle pressure of the finger at the lower end of the base-board carrying the objective and plate, is sufficient to move the telescope at the proper rate, and the co-operation of hand and eye during guiding seems soon to become almost automatic in character. When the instruments are stationary, the image of the star used for guiding, apparently travels many times faster than does the image of the star on the plate, owing to the magnification by the eyepiece; and for this reason any tendency to error in driving can be readily seen, especially with the enlarged star disc divided into four quadrants by crossed hairs in the eyepiece—long before such an error would be appreciable on the plate itself.

With the lens used, which was made by Hilger, and is uncorrected for photography, a field of good definition 5° square could readily be obtained.

An ordinary portrait lens of 2¼-inch aperture, mounted side by side with the 3½-inch refractor, gave very good results. One photograph of the Hyades, taken by its means, showed Neptune very distinctly.

The wooden dew-cap was found remarkably effective in keeping the object-glass clear, even when that of the guiding telescope, provided with a metal dew-cap, became bedewed.

When amateurs come to recognise that, with their small instruments, such a fruitful field for investigation is open to them, astronomy will probably be enriched by many discoveries which would otherwise be missed or delayed.

JOSEPH LUNT.

THE EXTINCT VERTEBRATES OF ARGENTINA.[1]

THE fossil vertebrata of South America are of peculiar interest to English palæontologists, since much of our earlier knowledge of the extinct mammals of that region is due to collections sent to this country by Sir Woodbine Parish and Darwin, and described by Owen, Clift, and others. These collections, however, valuable as they were, gave no idea of the extraordinary variety and abundance of the extinct fauna, the full importance of which has only been recognised of late years.

The terrestrial Mammalia of South America are, perhaps, the most remarkable and most strictly autochthonous in the world. If we except some marsupials as possibly Australian types and some comparatively recent immigrants, the whole of the mammals are peculiar. The American Edentata form a distinct order (for there is no reason for associating the Old World Manidæ and Orycteropidæ with them), and until the Upper Miocene (Loup Fork), they are entirely confined to the southern half of the continent. The other great divisions of the Mammalia are either represented by peculiar sub-orders or families, or, as in the case of the Insectivora, are entirely absent. Remains of this remarkable fauna are found in deposits of several horizons, which, in the wealth of species and individuals they contain, can only be compared to the Tertiary lake-basins of North America. In some cases the series seems to be sufficiently complete for the history of certain of the groups to be, at least partly, worked out, and it is to be hoped that the study of the development of these isolated types, taken in conjunction with the already clearly determined phylogenetic history of many North American groups, may lead to important generalisations as to the laws in accordance with which mammalian evolution has advanced. Unfortunately, up to the present, much less attention has been paid to points of morphological interest than to the making of new genera and species, many of which are founded on quite insufficient evidence, the result being that the nomenclature has been brought into an almost unparalleled state of confusion. It was with the intention of clearing up some of this confusion that, at the invitation of Dr. Moreno, Mr. Lydekker, in 1893–94, paid two visits to the La Plata Museum. The brief time at his disposal rendered it impossible for him to carry out his object with complete success, but he has nevertheless produced a work of the highest value, both from the purely original matter it contains, and also because it renders easily accessible descriptions and good figures of many little-known forms. Moreover, he has earned the gratitude of all students of mammalian palæontology by relegating to the synonymy a large number of imperfectly defined genera and species.

The first of the two volumes contains three memoirs, two of which consist of descriptions of new material, while the third is occupied by a revision of the Ungulata. The second, with the exception of a few supplementary pages on the Ungulates, and descriptions of two new species of Carnivora, is entirely devoted to the Edentata.

In the first memoir are described some Dinosaurian remains from Patagonia, the first recorded from South America. The most completely known form is a member of the Sauropodous group; it is referred to the genus Titanosaurus, species of which also occur in the Wealden of the Isle of Wight and in the Lameta beds of Central India; but since these are only known by caudal vertebræ, it seems very doubtful whether there is sufficient evidence to establish the generic identity of the South American species with them. Nevertheless the existence of a gigantic Sauropodous Dinosaur in Patagonia is certain; and this fact, together with the recently recorded discovery of a member of the same group in Madagascar, shows that these reptiles had extremely wide range during Jurassic and Cretaceous times in both the northern and southern hemispheres.

The second memoir deals with a number of Cetacean skulls from Patagonia. These are of great interest, both on account of the light some of them throw on the history of the group, and also because they show that the Santa Cruz beds are certainly later than the Eocene (to which they are assigned by the Argentine writers), and are probably Miocene. Physodon, a genus previously known only from teeth occurring in the Miocene and Pliocene of Belgium and England, and probably ancestral to the sperm whales (Physeter), is represented by *Physodon patagonicus*, which possessed a series of teeth in the upper jaw; these have entirely disappeared in the recent form. Another interesting species is *Prosqualodon australe*, a Squalodont remarkable for the small number of its molars and for its comparatively well-developed nasals, characters in which it approaches the Eocene Zeuglodonts more nearly than any toothed whale previously known. A primitive type of the Platanistidæ is also described. This memoir is an important addition to the history of the Cetacea, for although, as might have been expected from the age of the deposits, no light is thrown upon the difficult question of the origin of the group, the author is to be congratulated on having helped to fill some of the gaps in our knowledge of it.

The South American Ungulates appear to suffer from an extraordinary superfluity of names. Mr. Lydekker regards no less than ten generic terms as synonymous with Nesodon, and states that the number of specific names that have been applied to *Nesodon imbricatus* is countless. In the classification of the order the most important innovation is the establishment of a new sub-order, the Astrapotheria, for the reception of the Homalodontotheriidæ and the Astrapotheriidæ. It is suggested that the European genus Cadurcotherium may belong here; this seems very improbable, but if true is one of the most remarkable facts of distribution known. In the description of Astrapotherium there seems to be some doubt as to the nature of the immense upper tusks, since in one place they are said to be canines, while in the dental formula given they are put down as incisors. The sub-order Litopterna, adopted for the reception of the Proterotheriidæ and Macraucheniidæ, is regarded by the author as being intermediate between the Astrapotheria and the Perissodactyla, though not ancestral to the latter. Indeed there can be no doubt that the peculiar foot-structure of the Litopterna was acquired quite independently of the Perissodactyla, and that such points of resemblance as exist between them are merely due to parallelism of their lines of evolution, a cause of similarity often neglected.

[1] "Contributions to a Knowledge of the Fossil Vertebrates of Argentina." Parts I. and II. By R. Lydekker, F.R.S. (*Anales del Museo de la Plata*, "Palæontologia Argentina, II. and III.) Folio, La Plata. 1893-4.

Nearly half the second volume is devoted to the Glyptodontidæ. The author rejects the various subdivisions of this family suggested by Ameghino and adopted by Zittel, and refers all the species to six genera, some seventeen other generic terms being regarded as synonymous.

In this group the earlier forms are of comparatively small size, and it is only in the later (Pleistocene) deposits that such giants as *Glyptodon clavipes* and *Dædicurus clavicaudatus* are found. The same progressive increase in bulk is noticeable in other groups, *e.g.* in the Mylodonts and in the Litopterna among the Ungulates. It is not improbable that the great size of the Pleistocene species had much to do with their rapid extermination when some change in the environment took place.

The remainder of the memoir deals with the Dasypodidæ and Megatheriidæ; the latter family being given a somewhat wider scope than usual. The most interesting of the genera described is Eucholœops, which is probably ancestral to the Mylodonts and in some respects approaches Myrmecophaga.

These memoirs are illustrated by more than a hundred magnificent photographic plates, undoubtedly among the finest of their kind yet published; and while lithographic drawings by a competent artist are to be preferred for the representation of detail, such figures as those of the skeletons of Toxodon and of many of the Glyptodonts will not easily be surpassed.

The text is printed in English and Spanish in parallel columns: the English portion is unfortunately disfigured by very numerous misprints, doubtless owing to the fact that the author was compelled to entrust the correction of the proof-sheets to some person unfamiliar with the language.

THE EVOLUTION OF MODERN SCIENTIFIC LABORATORIES.[1]

THE scientific discoveries of the present century have had such a profound influence upon inventions, upon industries, and upon the comfort, health, and welfare of the people in general, that there is widespread, even if not always adequate, appreciation of the value of scientific study and investigation. But it may be doubted whether there is any proper understanding, in the minds even of the educated public, of the material circumstances which surround scientific discovery and which make it possible. The average man, if interested at all, is interested that the discovery is made, not how it is made.

In America, where men of science rely mainly upon enlightened private beneficence, and not upon governmental aid, to furnish the pecuniary resources which are essential for scientific progress, it is important that there should be some general information not only regarding the results of scientific work, but also regarding the external material conditions necessary for the fruitful prosecution of such work.

At the present day the systematic study and advancement of any physical or natural science, including the medical sciences, requires trained workers who can give their time to the work, suitably constructed work-rooms, an equipment with all of the instruments and appliances needed for the special work, a supply of the material to be studied, and ready access to the more important books and journals containing the special literature of the science.

All of these conditions are supplied by a well-equipped and properly organised modern laboratory. Such laboratories are, with the partial exception of the anatomical laboratory, entirely the creation of the present century, and for the most part of the last fifty years. They have completely revolutionised during the past half-century the material conditions under which scientific work is prosecuted. They are partly the result, and in larger part the cause, of that rapid progress of the physical and natural sciences which characterises the era in which we are living.

The evolution of the modern laboratory still awaits its historian. It is not difficult to find incidental references to historical facts bearing upon this subject. The development of the chemical laboratory has been traced with some fulness. But it is curious that there is no satisfactory monographic treatment of the general subject of the historical development of scientific laboratories. The subject seems to me an attractive one. It would surely be interesting to trace the development of the teaching and the investigating laboratory back to its beginnings, to learn about the material circumstances under which the physicists, the chemists, the morphologists, and physiologists of former generations worked. What share in the development of laboratories had the learned academies of the Renaissance and of the subsequent centuries? What share had public and private museums and collections of instruments of precision? What share had the work of the exact experimentalists, beginning with Galileo, of physicians, of the alchemists, and of the apothecaries? What individuals, universities, corporations, and governments were the pioneers in the establishment of laboratories for the various physical and natural sciences? The detailed consideration of these and many other questions pertinent to the subject would make an interesting and valuable historical contribution.

There is evidence that in Alexandria, under the early Ptolemies in the third century before Christ, there existed State-supported institutes, in which students of man and of nature could come into direct personal contact with the objects of study, and by the aid of such appliances as were then available could carry on scientific investigations. The practical study of anatomy, physiology, pathology, and other natural sciences was here cultivated. We are very imperfectly informed as to the results and the material circumstances of this remarkable period in the history of science. We know that after about a century of healthy activity the Alexandrian school gradually sank into a place for metaphysical discussions.

Fifteen hundred years elapsed before we next find any record of the practical study of a natural science. In 1231, the great Hohenstaufen, Frederick the Second, who has been called the most remarkable historic figure of the Middle Ages, commanded the teachers at Salernum diligently to cultivate the practical study of anatomy. After the passage of this edict occasional dissections of the human body were made, but it cannot be said that there was any diligent cultivation of anatomy on the part either of teachers or of students during the following two centuries.

In the latter half of the fifteenth century there developed that active interest in the practical study of human anatomy which culminated in the immortal work of Vesalius, published in 1543. After this the study of anatomy by dissections gradually assumed in the medical curriculum that commanding position which it has maintained up to the present day.

For over six hundred years there has been at least some practical instruction in anatomy, and for over three hundred years there have existed anatomical laboratories for purposes of teaching and of investigation, although only those constructed during the present century meet our ideas of what an anatomical laboratory should be. It is a matter of no little interest, both for the history of medicine and for that of science in general, that the first scientific laboratory was the anatomical laboratory. Private laboratories for investigation must have existed from the earliest times. Doubtless Aristotle had his laboratory. But the kind of laboratory which we have on this occasion in mind is one open to students or investigators, or both. There was no branch of physical or natural science, with the exception of anatomy, which students could study in the laboratory until after the first quarter of the present century. Only in anatomy could students come into direct contact with the object of study and work with their own hands and investigate what lay below the surface.

The famous Moravian writer on education, Amos Comenius, over two hundred and fifty years ago, gave vigorous expression to the conception of living, objective teaching of the sciences. He said, "Men must be instructed in wisdom so far as possible, not from books, but from the heavens, the earth, the oaks and the beeches—that is, they must learn and investigate the things themselves, and not merely the observations and testimonies of other persons concerning the things." "Who is there," he cries, "who teaches physics by observation and experiment instead of by reading an Aristotelian or other text-book?" But how little ripe were the conditions then existing for the successful carrying out of ideas so far in advance of his times is illustrated by the very writings of the author of "Orbis Pictus" and "Lux in Tenebris."

It would lead too far afield to trace in detail on this occasion the development of physical and of chemical laboratories, but on account of the intimate connection between the development of physics and chemistry and that of medicine, especially of more

[1] An address delivered at the opening of the William Pepper Laboratory of Clinical Medicine, Philadelphia, December 4, 1895, by Prof. William H. Welch.

exact experimental work in the medical sciences, a few words on this subject will not be out of place.

Methodical experimentation in the sciences of nature was definitely established by Galileo, and was zealously practised by his contemporaries and successors in the seventeenth century. It was greatly promoted by the foundation during this century of learned societies, such as the Accademia dei Lincei and the Accademia del Cimento in Italy, the Collegium Curiosum in Germany, the Académie des Sciences in Paris, and the Royal Society in England. Much of the classical apparatus still employed in physical experiments was invented at this period. Experimental physics from the first acquired a kind of fashionable vogue, and this aristocratic position it has ever since maintained among the experimental sciences. These sciences must concede to physics that commanding position which it has won by the genius of the great natural philosophers, by the precision of its methods and the mathematical accuracy of its conclusions, and by the fundamental nature and profound interest and importance of its problems. The debt of the medical sciences to the great experimental physicists, from Kepler and Galileo and Newton down to Helmholtz, is a very large one, larger than is probably appreciated by medical men who have not interested themselves in the history of experimental and precise methods in medicine.

There existed in the last century cabinets of physical apparatus to be used in demonstrative lectures, but they were very inadequate, and suitable rooms for experimental work scarcely existed. It was not until about the middle of the present century that we find the beginnings of the modern physical laboratory. Lord Kelvin, then William Thomson, established a physical laboratory in the University of Glasgow about 1845 in an old wine-cellar of a house. He tells us that "this, with the bins swept away, and a water supply and sink added, served as a physical laboratory for several years." It was as late as 1863 that Magnus opened in Berlin his laboratory for experimental physical research. Since 1870 there has been a rapid development of those splendid physical institutes which are the pride of many universities.

Humbler but more picturesque was the origin of the chemical laboratory. This was the laboratory of the alchemist searching for the philosopher's stone. In the painter's canvas we can still see the vaulted, cobwebbed room with its dim and mysterious light, the stuffed serpent, the shelves with their many-coloured bottles, the furnace in the corner with the fire glowing through the loose bricks, the fantastic alembics, the old alchemist in his quaint arm-chair reading a huge, worm-eaten folio, and the assistant grinding at the mortar. Fantastic and futile as it all may seem, yet here was the birth of modern chemistry. The alchemists were the first to undertake the methodical experimental investigation of the chemical nature of substances. No more powerful stimulus than the idea of the philosopher's stone could have been devised to impel men to ardent investigation. But search for gold was not all that inspired the later alchemists Paracelsus, the alchemist, that strange but true prophet of modern medicine as he was of modern chemistry, said, "Away with these false disciples who hold that this divine science, which they dishonour and prostitute, has no other end but that of making gold and silver. True alchemy has but one aim and object, to extract the quintessence of things, and to prepare arcana, tinctures, and elixirs which may restore to man the health and soundness he has lost." And again he says of the alchemists, "They are not given to idleness nor go in a proud habit or plush or velvet garments, often showing their rings upon their fingers, or wearing swords with silver hilts by their sides, or fine and gay gloves upon their hands, but diligently follow their labours, sweating whole days and nights by their furnaces. They do not spend their time abroad for recreation, but take delight in their laboratory. They wear leather garments with a pouch and an apron wherewith to wipe their hands. They put their fingers among coals and into clay, not into gold rings."

During the seventeeth and eighteenth centuries the doctrines and work of the alchemists had profound influence upon medicine. Alchemy was not completely overthrown until Lavoisier gave the death-blow to the phlogistic theory of Stahl. But for a considerable time before Lavoisier introduced the new spirit into chemistry, its methods and its problems were gradually approaching those of modern times. It was, however, over thirty years after the tragic death of Lavoisier before the first chemical laboratory in the modern sense was established. One cannot read without combined feelings of wonder and pity of the incommodious, forlorn, and cramped rooms in which such men as Scheele and Berzelius and Gay-Lussac worked out their memorable discoveries. Liebig has graphically described the difficulties encountered by the student of that day who wished to acquire practical training in chemistry. With some of the apothecaries could be obtained a modicum of practical familiarity with ordinary chemical manipulations, but Sweden and France were the centres for those with higher aspirations.

It was the memory of his own experiences which led Liebig, immediately after he was appointed professor of chemistry in Giessen in 1824, to set about the establishment of a chemical laboratory. Liebig's laboratory, opened to students and investigators in 1825, is generally stated to be the first modern public scientific laboratory. Although, as we shall see presently, this is not quite correct, it is certain that Liebig's laboratory was the one which had the greatest influence upon the subsequent establishment and organisation not only of chemical laboratories, but of public scientific laboratories in general. Its foundation marks an epoch in the history of science and of scientific education. This laboratory proved to be of great import to medical science, for it was here, and by Liebig, that the foundations of modern physiological chemistry were laid.

The significance of this memorable laboratory of Liebig is not that it was a beautiful or commodious or well-equipped laboratory, for it possessed none of these attributes—indeed, it is said to have looked like an old stable—but that here was a place provided with the needed facilities and under competent direction, freely opened to properly prepared students and investigators for experimental work in science.

The chemical laboratories of to-day are, in general, the best organised and the best supported of scientific laboratories.

The need of establishing physiological laboratories was recognised several years before the foundation of Liebig's laboratory. The important results to be derived from the application of the experimental method to the study of vital phenomena had been demonstrated first and most signally by Harvey, and after him by many experimenters. The fecundity of exact experimentation by physical and chemical methods applied to the phenomena of life had been shown by the classical researches of Lavoisier on respiration and animal heat. Magendie had entered upon that remarkable scientific career which entitles him to be regarded as the founder of modern experimental physiology, pathology, and pharmacology.

In 1812, Gruithuisen, who, after the custom of the times, filled an encyclopædic chair, being professor in Munich of physics, chemistry, zootomy, anthropology, and later of astronomy, published an article advocating the establishment of physiological institutes. In 1823, Purkinje, one of the most distinguished physiologists of this century, accepted the professorship of physiology in Breslau, this being the first independent chair of physiology in any German university. In 1824, Purkinje succeeded in establishing a physiological laboratory, which therefore antedates by one year Liebig's chemical laboratory in Giessen, although it cannot be said to have exercised so great an influence upon the organisation of scientific laboratories in general as did the latter. In 1840, Purkinje obtained a separate building for his laboratory.

With two or three exceptions, all of the separate physiological laboratories worthy of the name have been established since the middle of the present century. Bernard, that prince of experimenters, worked in a damp, small cellar, one of those wretched Parisian substitutes for a laboratory which he has called "the tombs of scientific investigators." There can be no greater proof of the genius of Bernard than the fact that he was able to make his marvellous discoveries under such obstacles and with such meagre appliances. France was long in supplying her scientific men with adequate laboratory facilities, but no more unbiassed recognition of the value and significance of the German laboratory system can be found than in the reports of Lorain, in 1868, and of Wurtz, in 1870, based upon personal study of the construction and organisation of German laboratories.

Of modern physiological laboratories, the one which has exerted the greatest and most fruitful influence is unquestionably that of the late Prof. Ludwig in Leipzig. This unequal position it has won by the general plan of its organisation, its admirable equipment, the number and importance of the discoveries there made, its development of exact methods of experimentation, the

personal character and genius of its director, and the number of experimenters there trained from all parts of the civilised world.

To-day every properly equipped medical school has its physiological laboratory. This department is likely to continue to hold its place as the best representative of exact experimental work in any medical science. A good knowledge of physiology is the best corrective of pseudo-scientific, irrational theories and practice in medicine.

Physiological chemistry has been an important department of research for over half a century, but it is only within recent years that there have been established independent laboratories for physiological chemistry. A large part of the work in this branch of science has been done hitherto in laboratories of general chemistry, of physiology, of pathology, and of clinical medicine. A physiological laboratory cannot well be without a chemical department, and the same is true of several other medical laboratories; but it seems to me that physiological chemistry has won its position as an independent science, and will be most fruitfully cultivated by those who with the requisite chemical and biological training devote their entire time to it. The usefulness of independent laboratories for physiological chemistry has been shown by the work done in Hoppe-Seyler's laboratory in Strassburg since its foundation in 1872. This was the first independent laboratory of physiological chemistry.

The first pathological laboratory was established by Virchow, in Berlin, in 1856. About this time he wrote: "As in the seventeenth century anatomical theatres, in the eighteenth clinics, in the first half of the nineteenth physiological institutes, so now the time has come to call into existence pathological institutes, and to make them as accessible as possible to all." It cannot be doubted that the time was fully ripe for this new addition to medical laboratories. Virchow secured his laboratory as a concession from the Prussian Government upon his return from Würzburg to Berlin. Virchow's laboratory has been the model as regards general plan of organisation for nearly all pathological laboratories subsequently constructed in Germany and in other countries. It embraced opportunities for work in pathological anatomy, experimental pathology, and physiological and pathological chemistry. This broad conception of pathology and of the scope of the pathological laboratory as including the study, not only of diseased structure, but also of disordered function, and as employing the methods, not only of observation, but also of experiment, should never be lost sight of.

The first to formulate distinctly the conception of pharmacology as an experimental science distinct from therapeutics and closely allied by its methods of work and by many of its problems to physiology, was Rudolph Buchheim. This he did soon after going to Dorpat in 1846 as extraordinary professor of materia medica, and it was apparently not long after he there became ordinarius in 1849 that he established a pharmacological laboratory in his own house and by his private means. Later, this laboratory became a department of the University, and developed most fruitful activity. Buchheim's laboratory was the first pharmacological laboratory in the present acceptation of this term. The conception of pharmacology advocated by Buchheim has been adopted in all German universities, and in not a few other universities; but it cannot be said to have been as yet generally accepted in the medical schools of this country and of Great Britain, although it seems destined to prevail.

The medical science which was the latest to find domicile in its own independent laboratory is hygiene. To Pettenkofer belongs the credit of first establishing such a laboratory. Since 1847 he had been engaged with hygienic investigations, and in 1872 he secured from the Bavarian Government the concession of a hygienic institute. This admirably equipped laboratory was opened for students and investigators in 1878. By this time Koch had already begun those epochal researches which, added to the discoveries of Pasteur, have introduced a new era in medicine. The introduction by Koch of new methods of investigating infectious diseases and many hygienic problems became the greatest possible stimulus for the foundation of laboratories of hygiene and bacteriology, and to some extent also of laboratories of pathology. The results already achieved by these new methods and discoveries in the direction of prevention and cure of disease, and the expectation of no less important results in the future, constitute to-day our strongest grounds of appeal to governments and hospitals and medical schools and the general public for the establishment and support of laboratories where the nature, the causes, the prevention, and the cure of disease shall be investigated. You have established in Philadelphia, and in connection with the Johns Hopkins University, the first hygienic laboratory in America, housed in its own building and assured, I believe, of a future of great usefulness.

It is apparent, from the brief and imperfect outline which I have presented of the evolution of modern scientific laboratories, that the birthplace of these laboratories, regarded as places freely open for instruction and research in the natural sciences, was Germany. Such laboratories are the glory to-day of German universities, which possess over two hundred of them. By their aid Germany has secured since the middle of the present century the palm for scientific education and discovery.

Great scientific investigators are not limited to any country or any time. There are those of surpassing ability who will make their own opportunity and will triumph over the most discouraging environment. This country and every civilised country can point to such men, but they are most exceptional. The great majority of those even with the capacity for scientific work need encouragement and opportunity. We now have sufficient knowledge of the workings of scientific laboratories to be able to assert that in general where the laboratory facilities are the most ample and the most freely available, there are developed the largest number of trained workers, and there the discoveries are the most numerous and the most important. At the present day no country, no university, and no medical school can hold even a respectable place in the march of education and progress unless it is provided with suitable laboratories for scientific work.

A properly equipped and properly conducted scientific laboratory is a far more expensive institution than is usually conceived. It must be suitably domiciled either in a separate building or in rooms commodious and well-lighted. The outside architectural features are of secondary importance. The instruments and appliances necessary for exact observation and experiment, even in those sciences which apparently require the least, are numerous and costly. A working library, containing the books and sets of journals most frequently consulted, is most desirable, if not absolutely indispensable. The director of the laboratory should be a man of ability and experience, who is a master in his department of science. He must have at least one assistant, who is preferably a young man aiming to follow a scientific career. A person of no small value in the successful working of the laboratory is the intelligent janitor or "diener," who can be trained to do the work of a subsidiary assistant and can be entrusted with the care and manipulation of instruments. There must be funds for the purchase of fresh supplies and new instruments when needed. The running expenses of a first-class laboratory are not small.

But, costly as may seem the establishment and support of a good laboratory, the amount of money expended for laboratories would seem to us ridiculously insignificant if we could estimate the benefits to mankind derived from the work which has been done in them. Wurtz has truly said of the money required for laboratories, "It is a capital placed at a high rate of interest, and the comparatively slight sacrifice imposed upon one generation will bring to following generations increase of well-being and knowledge."

The educational value of the laboratory cannot well be overestimated. For the general student this is to be found primarily in the development of the scientific habit of thought. He learns that to really know about things it is necessary to come into direct contact with them and study them. He finds that only this knowledge is real and living, and not that which comes from mere observation of external appearances, or from reading or being told about things, or, still less, merely thinking about them.

The problem of securing for the student of medicine the full benefits of laboratory instruction in the various medical sciences is a difficult one, and cannot, I believe, be solved without considerable readjustment of existing schemes of medical teaching; but this subject is one which I cannot attempt to consider here.

The whole face of medicine has been changed during the last half-century by the work of the various laboratories devoted to the medical sciences. Anatomy, physiology and pathology now rank among the most important of the sciences of nature. They have been enriched with discoveries of the highest significance and value not only for medicine, but also for general biology. Although we have not penetrated, and perhaps may never penetrate, the mystery of life, we are coming closer and closer to an understanding of the intimate structure and the

fundamental properties of living matter. We already know that living matter is not that homogeneous, formless substance which, not many years ago, it was believed to be, but that it possesses a complex organisation.

Practical medicine has been profoundly influenced by the unparalleled development of the medical sciences during the last fifty years, and especially during more recent years. Scientific methods have passed from the laboratory to the hospital. Cases of disease are now studied with the aid of physical and chemical and microscopical and bacteriological methods. The diagnosis of disease has thereby been greatly advanced in precision, and if Boerhaave's motto, *qui bene diagnoscit, bene medebitur*, be true, there should be a corresponding advance in the results of the treatment of disease. Whether or not this dictum of the old master be true—and I have serious doubts as to its entire truth—it cannot be doubted that great progress has been made in medical, and especially in surgical treatment as a result of scientific discoveries, although the treatment of disease still rests, and will doubtless long continue to rest, largely upon empirical foundations.

We are assembled here to-day to assist at the opening of a laboratory which gives the fittest and strongest possible expression to the influence of scientific work upon practical medicine. The generous founder has marked with characteristic insight the direction in which the current is setting.

The conception of a thoroughly equipped laboratory as an integral part of a hospital and intended for the study and investigation of disease is of recent origin. The germs of this idea, however, may be traced back to such men as Hughes Bennett and Beale in Great Britain, and to Frerichs and Traube in Germany, who in their hospital work made fruitful application of microscopical, chemical, and experimental methods. A little over ten years ago, von Ziemssen, in Munich, established a well-conceived clinical laboratory, containing a chemical, a physical, and a bacteriological department, a working library, and rooms for practical courses and the examination of patients. A similar laboratory was secured by Curschmann in Leipzig in 1892.

The growing recognition of the need of such laboratories is the result of the great progress in scientific medicine during recent years. The thorough clinical examination of many cases of disease now requires familiarity with numerous technical procedures, physical, chemical, microscopical, and bacteriological. The laboratory outfit required simply for routine clinical examinations is considerable. A microscope and a few test tubes and chemical reagents for simple tests of the urine no longer suffice. As illustrations of this, I call attention to the clinical value of examinations of the blood, of the contents of the stomach, of fluids withdrawn from the serous cavities, of the sputum and various secretions, of fragments of tissue removed for diagnosis. Such examinations require much time, trained observers, and considerable apparatus. To secure for the patients the benefits in the way of diagnosis, prognosis, and treatment to be derived from these methods of examination, a hospital should be supplied with the requisite facilities.

A hospital, and especially one connected with a medical school, should serve not only for the treatment of patients, but also for the promotion of knowledge. Where this second function is prominent, there also is the first most efficiently and intelligently carried out. Herein we see the far-reaching beneficence of a laboratory, such as this one, thoroughly equipped to investigate the many problems which relate to clinical medicine.

The usefulness of an investigating laboratory in close connection with a hospital has already been abundantly demonstrated. Chemical studies, more particularly those relating to metabolism in various acute and chronic affections, microscopical and chemical investigations of the blood and bacteriological examinations of material derived directly from the patient, may be mentioned as directions in which researches conducted in hospital laboratories have yielded important results and will garner still richer harvests in the future.

There need be no conflict between the work of clinical laboratories and that of the various other medical laboratories. Each has its own special field, but it is not necessary or desirable to draw around these fields sharp boundary lines beyond which there shall be no poaching. It will be a relief to pathological and other laboratories to have certain examinations and subjects relating directly to practical medicine consigned to the clinical laboratory, where they can receive fuller and more satisfactory consideration. The subject-matter for study in the clinical laboratory is primarily the patient and material derived from the patient. Anatomical, physiological, pathological, pharmacological, and hygienic laboratories must concern themselves with many problems which have apparently no immediate and direct bearing upon practical medicine. In the long run their contributions are likely to prove most beneficial to medicine if broad biological points of view, rather than immediate practical utility, are their guiding stars. The clinical laboratory will concern itself more particularly with questions which bear directly upon the diagnosis and the treatment of disease.

To the small number of existing well-equipped clinical laboratories the William Pepper Laboratory of Clinical Medicine is a most notable addition. It is the first laboratory of the kind provided with its own building and amply equipped for research in this country, and it is not surpassed in these respects by any in foreign countries. It is intended especially for investigation and the training of advanced students. It is a most worthy memorial of the father of its founder.

William Pepper the elder was a very distinguished physician and trusted consultant of Philadelphia, for many years an attending physician at the Pennsylvania Hospital, where he was a clinical teacher of great influence, and for four years the professor of the theory and practice of medicine in this University. He belonged to that remarkable group of American physicians, trained under Louis, who brought to this country the best methods and traditions of the French school of medicine at the time of its highest glory. His diagnostic powers are said to have been remarkable. With his broad sympathies, his lofty ideals, and his active and enlightened efforts for the promotion of clinical medicine, how he would have welcomed such opportunities as will be afforded by this laboratory to contribute to a better knowledge of the nature, the diagnosis, and the treatment of disease!

Our country has until within a very few years been deprived of the encouragement and opportunities for original investigations in the medical sciences afforded by large and thoroughly equipped laboratories. We can still count upon the fingers of one hand our medical laboratories which are comparable in their construction, organisation and appliances to the great European laboratories. Notwithstanding these obstacles, there have been American physicians of whose contributions to medical science we may feel proud.

But a new era has dawned. Of that we are witnesses here to-day. The value of medical laboratories is now widely recognised among us. To those of us who appreciate the underlying currents in medicine, who follow with eager interest the results of the almost feverish activities in foreign laboratories, who recognise the profound interest and importance of the many medical problems which await only patient investigation and suitable facilities for their solution, and who would like to see our country take the prominent position it should in these investigations, our laboratories may seem slow in coming, but they will in time be provided by enlightened benevolence. The individual or institution or hospital which contributes to the establishment of a good laboratory devoted to any of the medical sciences merits in unusual degree the gratitude of all medical men; yes, of every true friend of humanity. Such gratitude we feel for the generous and public-spirited founder of this laboratory, who has contributed largely to the advancement of medicine in this country, and of whose splendid services to this university I need not speak in this presence.

I congratulate this city and this university and this hospital upon the important addition made by this laboratory to higher medical education and the opportunities for scientific work in this country. May the enlightened aims of the founder, and the hopes of all interested in the promotion of medicine in this country, be fulfilled by the scientific activities which will now begin in the William Pepper Laboratory of Clinical Medicine.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—At the Encænia this year (June 24) it will be proposed to confer the honorary degree of D.C.L. upon Sir Archibald Geikie, among others.

The Rolleston memorial prize has been awarded to Mr. Horace M. Vernon, for his dissertations on (1) the effect of environment

on the development of Echinoderm larvæ, (2) the relation of the respiratory exchange of cold-blooded animals to temperature, (3) the respiratory exchange of the lower marine invertebrates.

CAMBRIDGE.—The Reade Lecture will be given on Wednesday, June 10, in the Anatomy Theatre, by Prof. J. J. Thomson. The subject for this year is "Röntgen Rays."

Prof. Lewis announces a course of lectures and demonstrations in Crystallography, to be given daily during the Long Vacation, beginning on July 8.

A new syndicate, to take the place of that rejected by the Senate last term, has been nominated to consider the question of degrees for women. It consists of the Vice-Chancellor, Dr. C. Taylor, Mr. W. Chawner, Dr. V. Stanton, Dr. F. W. Maitland, Dr. L. E. Shore, Dr. M. James, Prof. Robinson, Mr. J. W. Cartmell, Mr. R. D. Roberts, Mr. W. N. Shaw, F.R.S., Mr. A. W. W. Dale, Mr. A. N. Whitehead, and Mr. A. Berry. This list includes only three members of the Council, and is said to be younger and less partisan than the rejected syndicate.

Meanwhile Dr. Hobson, F.R.S. of Christ's College, has issued a fly-sheet proposing that, as the balance of opinion in the Senate is against the admission of women to full membership, it might suffice to confer on them the "title" of B.A. by diploma. The title, he thinks, should be open to women who have studied at recognised colleges other than Newnham and Girton, provided they pass one of the Tripos examinations. It remains to be seen what reception will be given by Newnham and Girton to this proposal for an encroachment on their monopoly.

The Statute authorising the University to make provision for Advanced Students has received the approval of the Queen in Council. A guide to the courses of advanced study and research at present arranged for, has been prepared by Dr. Donald MacAlister, Tutor of St. John's College, and will be issued in June by the University Press.

A STRENUOUS and persistent effort to endow Barnard College (for women) has just been successfully made. The college some months ago purchased a site adjoining the new site of Columbia University, paying 160,000 dols., of which sum 100,000 dols. remained on mortgage. An unknown benefactor offered to pay the amount of this mortgage, provided others would contribute an equal amount by May 10. It is now known that this benefactor is Mrs. Van Wyck Brinkerhoff. Another unknown donor, who turns out to be Mr. John D. Rockefeller, offered 25,000 dols.; others contributed smaller amounts, but on the morning of Saturday, May 9, there was still a deficit of 23,000 dols. By strenuous efforts, however, this was secured during the day. Among the contributors were Mr. Seth Low, Mrs. F. E. Hockley, and an anonymous friend, who each paid 10,000 dols., and Mr. Jacob H. Schiff, who paid 8000 dols.

WE notice that at the last meeting of the Oxfordshire County Council, held at Oxford on the 12th inst., a proposition was made to devote the sum of £2000 out of a total of £4080, arising from the Customs and Excise Duties, to the relief of the rates; but it was defeated by a large majority. At a meeting of the East Sussex County Council, held on the same day, a resolution was carried that the whole of the funds available for the purposes of technical education be in future devoted to this object, instead of £5000 as heretofore. A similar motion was proposed at the meeting of the County Council for the North Riding of Yorkshire, held on the 6th inst. at Northallerton, and gave rise to a considerable amount of discussion, during which one councillor, a prominent member of Parliament, described the Technical Instruction Committee as the "horse-leech of the Council." Eventually an amendment, "that the County Council devote £6000 of the Local Taxation (Customs and Excise) grant for 1896-7 to technical education," was carried unanimously. By referring we find that during the financial year 1893-4 the total amount available was £6928.

THE last number of the *London Technical Education Gazette* gives some very interesting information concerning the number of scholarships and exhibitions which have been awarded by the Technical Education Board of the London County Council. The total number of the Board's scholars and exhibitioners is 1752, of whom 1154 are junior, 118 are intermediate, and 10 senior county scholars. The reports, which the Board receives at regular intervals, show that in the majority of cases the conduct and progress of the scholars are satisfactory. Some scholars have done remarkably well, especially in the case of the intermediate and senior students. In the case of a few of the junior scholars it has been found necessary to give a caution and to renew their scholarships for a short time on probation. This has in most cases been quite enough, though one or two scholarships have had to be taken away entirely. The scholarship winners are left free to choose any school that appears on the Board's published list. The result is, that at present 913 junior county scholars are in attendance at secondary schools, and 241 at upper standard public elementary schools. The secondary schools most commonly chosen are Roan School, Owen's School, Alleyn's School, and Aske's School, Hatcham, at all of which there are over fifty scholars and exhibitioners. The intermediate county scholars are now attending all the principal secondary schools of London, and some are in attendance at institutions of university rank, after having been for a year at a secondary school. The senior county scholars have joined some of the principal universities of the country, two being at Cambridge, at Clare and Sidney Sussex Colleges, and two at Newcastle in connection with the University of Durham.

THE report of the Technical Instruction Committee, which was presented to the May meeting of the West Riding Council, supplies abundant evidence of the good work which has been done during the session which is being completed. As would be expected, a very important place is occupied by the Committee's consideration of the Education Bill, an excellent summary of which forms the opening part of the report. The conclusions to which the Committee have come are that it would be undesirable for the duties connected with the administration of elementary education to be placed upon County Councils and for any expenditure in reference to such instruction to be thrown upon the County rates. The proposals with reference to secondary education are very favourably regarded, but it is pointed out that already the expenditure exceeds the income provided under the Local Taxation (Customs and Excise) Act, 1890, and must necessarily increase; and hence, if the County Council is to utilise the extended powers and carry out the duties to be conferred by the Bill, it is essential that adequate moneys be provided by Parliament. They further recommend that the Education Department should not be endowed with additional powers of control over the County Council in respect of the expenditure of funds provided under the above-mentioned Act, or out of the County rate for purposes of secondary education. We would call especial attention to certain supplementary regulations which have been adopted by the Committee as to the award and tenure of technical exhibitions. In future the Committee will, in considering recommendations for exhibitions, have regard to the preparatory work already done by the student, and as a rule no technical exhibition will be awarded unless evidence can be given by the candidate that he possesses a satisfactory knowledge of the principles of those sciences on which such technological subject is based; for instance, an exhibition in electric lighting and power distribution would in no instance be awarded to a student possessing an inadequate knowledge of applied mechanics and electricity and magnetism. No exhibition will usually be granted for a study of a *technological* subject to an applicant under eighteen years of age. These are but examples of a number of really wise provisions.

SCIENTIFIC SERIALS.

American Journal of Science, May.—Carbon and oxygen in the sun, by J. Trowbridge. The peculiar bands of the arc spectrum of carbon can be detected in the sun's spectrum. They are, however, almost obliterated by the overlying absorption lines of other metals, especially by the lines due to iron. In order to form an idea of the amount of iron in the atmosphere of the sun which would be necessary to obliterate the banded spectra of carbon, the author compared the spectrum of carbon with that of carbon dust and a definite proportion of iron distributed uniformly through it. The carbon dust and iron reduced by hydrogen was formed into pencils suitable for forming the voltaic arc, and containing 28 per cent. of iron to 72 per cent. of carbon. Photographs were taken of the portion of the solar spectrum which contains traces of the peculiar carbon band lying at wave-length 3883·7. The pure carbon-banded spectrum was photographed on the same plate immediately below the solar spectrum, and the spectrum of the mixed iron and carbon immediately below this. It was found that the iron present almost completely obliterated the carbon, and this fact tells in favour of

the supposition that the traces of bands observed are true carbon bands. The author also investigated the spark spectrum of oxygen produced by a dynamo and transformer, and compared the bright lines found with the solar iron lines found in the same positions. The result showed that the oxygen lines, if present in the sun, are not sufficient to cover even the faintest iron absorption lines. Still, the author inclines to the view that the sun's light is due to carbon vapour in an atmosphere of oxygen.—On the determination of the division errors of a straight scale, by H. Jacoby. The author compares every division, and set of divisions, microscopically with every division on a duplicate scale. This is Gill's method. But he improves it by counting the "weight" of each observation according to its true value, instead of assigning the same weight to all readings without distinction.—Röntgen rays not present in sunlight, by M. Carey Lea. The author proved this by trying to obtain radiographs from the sun's light through one hundred leaves of a book, or through aluminium foil. No trace of Röntgen rays was found in sunlight, nor was any found in the light from a Welsbach incandescent gas burner.—On numerical relations existing between the atomic weights of the elements, by M. Carey Lea. It has already been shown that elements whose ions are always colourless can be arranged in vertical lines so that the horizontal lines contain each a natural group. Also that the elements whose ions are always coloured, form series with the atomic weights immediately following one another. If the atomic weights in the first vertical column are subtracted from those in the second, the second from the third, and so on, certain standard differences are found to recur. One of these is about 16, the other about 46, and the third about 88. The elements with ions always coloured are outside of this rule. Their behaviour is altogether anomalous. The colourless elements, beginning with hydrogen, fall into four series of nine each, interrupted by four coloured groups, and followed by an alternate series, Hg, Tl, Pb, Bi, Th and U.

Bulletin of the American Mathematical Society, April.—A two-fold generalisation of Fermat's theorem, a paper presented to the Society at its February meeting, is stated by the author, Prof. E. H. Moore, to be one-fold generalisations of two known theorems, of which one may be looked at as a theorem in the ordinary Gauss-congruence theory, while its generalisation is a theorem in the Galois-field theory. It is naturally highly symbolical. Prof. J. Pierpont gives an interesting and valuable note on the Ruffini-Abelian theorem. Gauss, in 1799, rigorously established the fundamental theorem that every equation of degree n possesses n roots real or imaginary. When n is less than five, it had been long known that these roots could be expressed as explicit algebraic functions of the coefficients. Between the years 1799 and 1813 an Italian mathematician, Ruffini, made several attempts to establish the justice of the doubts that the roots of equations of degree greater than four possessed this property. His reasoning, however, has not been judged to be conclusive, and the question remained open until the publication of Abel's argument in 1826. Prof. Pierpont, in addition to the preceding statement, gives several other historical notes, and states that his object is to give a demonstration of the theorem which shall be as direct and *self contained* as possible. In addition he gives demonstrations, one of which is a modification of Ruffini's form, and the other Kronecker's modification of Abel's form.—On certain subgroups of the general projective group, is a paper, read before the January meeting, by the author, Prof. Henry Taber. It is on the lines of recent previous papers by the author in the *Bulletin*, the *Proceedings* of the London Mathematical Society, and the *Mathematische Annalen*. The "Notes" give the courses for the summer semester at Berlin and Göttingen. A synopsis is also published of the first volume of a work of great originality, viz. the Geometrie der Berührungstransformationen, Dargestellt von Sophus Lie und G. Scheffers. A long list of new publications closes the number.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 30.—"On some Palæolithic Implements found in Somaliland by Mr. H. W. Seton-Karr." By Sir John Evans, K.C.B., F.R.S.

In the course of more than one visit to Somaliland, Mr. Seton-Karr noticed, and brought home for examination, a number of worked flints, mostly of no great size, which he laid before the Anthropological Section of the British Association, at the meeting last year at Ipswich.[1] Although many of these specimens were broad flat flakes trimmed along the edges so as to be of the "le Moustier type" of M. Gabriel de Mortillet, and although the general *facies* of the collection was suggestive of the implements being of Palæolithic age, they did not afford sufficient evidence to enable a satisfactory judgment to be formed whether they undoubtedly belonged to the Palæolithic period.

On returning to Somaliland, during the past winter, Mr. Seton-Karr was fortunate enough to meet with a large number of specimens in form absolutely identical with some from the valley of the Somme and other places.

Of this identity in form there can be no doubt, and though at present no fossil mammalian or other remains have been found with the implements, there need be no hesitation in claiming them as Palæolithic. Their great interest consists in the identity of their forms with those of the implements found in the Pleistocene deposits of North Western Europe and elsewhere.

The discovery aids in bridging over the interval between Palæolithic man in Britain and in India, and adds another link to the chain of evidence by which the original cradle of the human family may eventually be identified, and tends to prove the unity of race between the inhabitants of Asia, Africa, and Europe, in Palæolithic times.

May 7.—"The Electromotive Properties of the Electrical Organ of *Malapterurus electricus*." By Francis Gotch, F.R.S., and G. J. Burch.

The conclusions drawn by the authors from the experiments on the isolated organ and on the entire uninjured fish may be summarised as follows :—

(1) The isolated organ responds to electrical excitation of its nerves by monophasic electromotive changes, indicated by electrical currents which traverse the tissue from the head to the tail end; this response commences from 0·0035″ at 30° C. to 0·009″ at 5° C. after excitation, the period of delay for any given temperature being tolerably constant.

(2) The response occasionally consists of a single such monophasic electromotive change (shock) developed with great suddenness, and subsiding completely in from 0·002″ to 0·005″, according to the temperature; in the vast majority of cases the response is multiple, and consists of a series of such changes (shocks) recurring at perfectly regular intervals, from two to thirty times (peripheral organ rhythm); the interval between the successive changes varies from 0·004″ at 30° C. to 0·01 at 5° C., but is perfectly uniform at any given temperature throughout the series.

(3) Such a single or multiple response (in the great majority of cases the latter) can also be evoked by the direct passage of an induced current through the organ and its contained nerves, in either direction heterodromous (*i.e.*, opposite in direction to the current of the response) or homodromous.

(4) The time relations of the response are almost identical whether this is evoked by nerve-trunk (indirect stimulation), or by the passage of the heterodromous induced current.

(5) There is no evidence that the electrical plate substance can be excited by the induced current apart from its nerves, *i.e.* it does not possess independent excitability.

(6) The organ and its contained nerves respond far more easily to the heterodromous than to the homodromous induced current, and the period of delay in the case of the latter response is appreciably lengthened.

(7) The peripheral organ rhythm (multiple response) varies from about 100 per second at 5° C. to about 280 per second at 35° C.

(8) One causative factor in the production of the peripheral rhythm is the susceptibility of the excitable tissue to respond to the current set up by its own activity (self-excitation).

The authors further conclude that, since each lateral half of the organ is innervated by the axis cylinder branches of one efferent nerve cell, and has no independent excitability, the specific characters of the reflex response of the organ express far more closely than those of muscle the changes in central nerve activity, and are presumably those of the activity of a single efferent nerve cell.

The single efferent nerve cell, the activity of which is thus for the first time ascertained, shows—

(*a*) A minimum period of delay of 0·008″ to 0·01″.

(*b*) A maximum rate of discharge of 12 per second.

[1] Report 1895 p 824

(*c*) An average rate of discharge of 3 to 4 per second.

(*d*) A susceptibility to fatigue showing itself in the discharge failing after it had recurred from two to five times at the above rates.

Physical Society, May 22.—Prof. Ayrton, Vice President, in the chair.—Mr. R. Appleyard read a paper on dielectrics. The author has particularly investigated the effect of temperature on dielectric resistance. He has employed for this purpose condensers insulated with mica and paraffined paper. In order to eliminate some of the effects of surface leakage, Price's guard-ring arrangement was made use of in all the experiments. The author finds that the capacity of a paraffin condenser varies irregularly with the temperature, but that to within the accuracy attainable with his instruments (1 per cent.), the capacity of a mica condenser is constant between 33° F. and 110° F. If the resistance of paraffin at a temperature t is represented by $R_t = R\alpha^t$, the mean value for log α deduced from all the author's measurements is $\bar{1}\cdot96344$. Experiments made with a parallel plate condenser with paraffin as the dielectric, show that when the temperature reaches within about 20° of the melting point the resistance rapidly falls; when melting commences there is a rapid drop, but while melting is in progress the resistance remains constant. Prof. Ayrton said he could bear witness to the extreme value of Mr. Price's device, as it completely did away with the necessity for the extreme care previously necessary to prevent errors due to surface leakage. He regretted that he had not had an opportunity of comparing the author's numbers with some obtained some years ago by Prof. Perry and himself (Prof. Ayrton).—A paper by Prof. Viriamu Jones, on the magnetic field due to an elliptical current at a point in the plane of the ellipse and within it, was taken as read. Prof. Silvanus Thompson said that this paper was of interest not only on account of the application which others might make of the author's method, but also in that the correction when applied to Prof. Jones's results brought the international ohm more nearly into accord with the true ohm. Mr. J. J. Walker said he considered that the paper was more suited to the Mathematical Society. The integration which the author reduced to elliptic integrals might be more easily performed by another method. Prof. Ayrton said that Prof. Jones's value for the true ohm was now 106·302 cm. of mercury.—Mr. Campbell read a paper on new instruments for the direct measurement of the frequency of alternating or pulsating electric currents. The author employs two arrangements, in one of which a steel wire, the tension on which is variable, and the other a steel spring of variable length, clamped at one end, are acted upon by an electro-magnet, through which the periodic current is passed. The tension or length, as the case may be, is varied till maximum resonance is obtained, a small contact piece being employed to detect when this occurs. The instrument exhibited was capable of measuring the frequency of periodic currents of from 40 to 150 double vibrations per second. Mr. Watson said he thought that in the case of the steel spring there would be a considerable temperature correction, and he suggested a method by which this might be compensated. Mr. Blakesley asked if the author had found that the spring became magnetised and thus gave the octave. Mr. Carter asked whether elastic fatigue influenced the results, and said that a synchronous motor and a speed indicator could be used to measure the frequency. Prof. Silvanus Thompson suggested that it might be preferable to employ a polarised apparatus, since to avoid the impression of forced vibrations on the spring it was better, as was done in the case of tuning-forks, to make it massive. It had been found in other cases, such as in Hughes' telegraph and the telephone, that better results were obtained with polarised apparatus. He (Prof. Thompson) had used a telephone, placed anywhere near a magnet traversed by the periodic current, together with a tuning-fork, which gave beats with the note produced by the telephone, to measure frequencies. The variations in frequency ordinarily met with in practice were much greater than was generally suspected. Mr. Blakesley said he considered that the advantage of the author's instrument over a telephone and tuning fork was that it was continuously variable over a large range. Mr. Enright asked if the author had been troubled by the spring or wire breaking into overtones. In some experiments in which rather long wires were used, he had been troubled in this way. Prof. Ayrton said that he did not think that it was possible to get the wire or spring to respond to the octave unless the alternating current contained a component of the frequency of the octave; in fact, he had himself used such a stretched string as a wave analyser. He had used a telephone to prove that the note given by a hissing alternate current arc corresponded in frequency to that of the current. In the instrument used by Prof. Perry and himself, a polarised arrangement was always employed, since the alternating current was passed either through a wire in a constant magnetic field, or through an electro-magnet which acted on a wire through which a constant current was passed. The author, in his reply, said that the instrument responded, though feebly, to the octave, and this response might be made use of to check the accuracy of the scale.—The Society then adjourned till June 12.

Entomological Society, May 6.—Prof. Meldola, F.R.S., President, in the chair.—Mr. Champion exhibited specimens of *Amara famelica*, Zimm., from Woking, Surrey, a recent addition to the British list. He also exhibited, on behalf of Mr. Dolby-Tyler, a series of *Eburia quadrinotata*, Latr., from Guayaquil, Ecuador, showing variation in the number of the raised ivory-white lines on the elytra.—Mr. Horace Donisthorpe exhibited a specimen of *Pterostichus gracilis* with three tarsi on one leg, taken near Weymouth last April.—Mr. G. T. Porritt exhibited a series of *Arctia menthrastri* which he had just bred from Morayshire ova; the ground-colour of the specimens varied from the usual white, through shades of yellow, to dark smoky-brown.—Mr. Merrifield exhibited specimens of *Gonepteryx rhamni* bred from larvæ found in North Italy and Germany, the pupæ of which had been subjected to various temperatures. He stated that high temperature appeared to cause an increase of yellow scales in the female, and low temperatures generally reduced the size of the orange discal spot on the forewings of both sexes.—Mr. Merrifield said that the effects on the imago produced by temperature were being made the subject of systematic research by Prof. Weismann, Dr. Standfuss, Mr. E. Fischer, and others.—Mr. Kirkaldy exhibited and made remarks on ova of *Notonecta glauca* var. *furcata*.—Mr. Tutt exhibited living larvæ of *Apamea ophiogramma*, together with the grass on which it was feeding.—Mr. Goss read a communition from Mr. E. Meyrick on the subject of Prof. Radcliffe-Grote's criticisms, contained in his paper published in the *Proceedings* of the Society, 1896, pp. x.-xv., on the use of certain generic terms by Mr. Meyrick in writing on the Geometridæ.—Mr. McLachlan opened a discussion as to the best means of preventing the extinction of certain British butterflies. He referred to the extinction of *Chrysophanus dispar*, *Lycæna acis*, and *Aporia cratægi*, and to the probable extinction, in the near future, of *Papilio machaon*, *Melitæa cinxia*, and *Lycæna arion*. He stated that one of the objects he had in view in bringing this matter forward was to see whether some plan could not be devised to protect those specially localised species which were apparently in danger of being exterminated by over-collecting.—Prof. Meldola said he fully sympathised with the remarks of Mr. McLachlan, and thought that a resolution passed by the Society, possibly in conjunction with kindred Societies, might produce some effect. Mr. Goss stated that *Papilion machaon*, although apparently doomed to extinction in its chief locality in Cambridgeshire (Wicken Fen), would probably linger on in the country in smaller fens, such as Chippenham, where the larvæ had been found feeding on *Angelica sylvestris*. It would certainly survive in the Norfolk Broads, both from the irreclaimable nature of the fens there and the extensive range of the species in the district. He stated that *Melitæa cinxia*, although gradually disappearing from most of its old localities in the south of the Isle of Wight, was still found in the island further west, where he had seen it in numbers in May 1895. He added that *Lycæna arion* was far from extinct in Gloucestershire, and was distributed over a much wider area in the extreme south-west of England than was generally supposed.—Mr. Elwes stated that *L. arion* formerly occurred in several places on his own property in Gloucestershire, but had disappeared of late years, although not collected. Its disappearance was probably due to changes of climate.—Colonel Irby said that *L. arion* had disappeared many years ago not only from Barnwell Wold, Northamptonshire, but from another part of the county, on the estate of Lord Lilford, not accessible to the public, and that its disappearance there was no doubt caused by the destruction of the food plant and other herbage by burning the pasture, and by the grazing of sheep. Mr. Crowley, Mr. Tutt, Mr. Waterhouse, and Mr. Blandford continued the discussion.—Mr. Guy A. K. Marshall communicated a paper entitled "Notes on Seasonal Dimorphism in South African Rhopalocera."—Mr. P. Cameron communicated a paper entitled "Descriptions of new species of Hymenoptera from the Oriental Region."

Geological Society, May 13.—Dr. Henry Hicks, F.R.S., President, in the chair.—An account of a head or gateway driven into the Eastern Boundary-fault of the South Staffordshire coal field, by William Farnworth. The author described certain peculiarities observed during the driving of a head towards the fault separating the Coal-Measures and Permian rocks, from a pit situated four miles east of Walsall, at the southern extremity of the Cannock Chase coal field.—On the geographical evolution of Jamaica, by Dr. J. W. Spencer. The object of the paper was to set forth the physical and geological characteristics of Jamaica which bear upon the problem of its late high elevation and former connection with the continent, and to trace across the neighbouring seas and islands to the mainland the evidences of the former linking of Jamaica to North and South America. The first part of the paper treated of the growth of the island. The second part of the paper treated of the continental connections of Jamaica. The author gave details of the submerged plateaus and drowned valleys which are analogous to those still existing above sea-level. They indicate that the former altitude of the West Indian plateau, and some portions of the adjoining continent, reached two and a half miles. But the floors of the Mexican Gulf and Honduras and the Caribbean Sea formed low plains draining into the Pacific Ocean, for at that time the eastern region was high, while the Mexican area was generally low.—Dundry Hill: its upper portion, or the beds marked as Inferior Oolite (G 5) in the maps of the Geological Survey, by S. S. Buckman and E. Wilson. The authors gave an account of previous geological work relating to Dundry Hill, especially that which refers to the correlation of its strata. Then they described the different exposures on the hill, together with the results of various excavations carried out by quarrymen under their superintendence for the purpose of the present communication. Besides demonstrating the sequence of the strata of Dundry Hill, the authors were able to show a number of results of special interest.

Zoological Society, May 19.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—Mr. Sclater exhibited a daguerreotype portrait of what was believed to be the first gorilla that was ever brought alive to Europe. It was living in Wombwell's menagerie in 1855. This portrait had been lent to Mr. C. Bartlett by Mr. Fairgrieve, formerly associated with Mr. Wombwell, who had sent with it an account of the animal and its habits.—A communication was read from Mr. G. E. H. Barrett-Hamilton, on a variation in the pattern of the teeth of a specimen of the common field-vole (*Microtus agrestis*).—A second communication from Mr. Barrett-Hamilton contained remarks on the existence in Europe of two geographical races or sub-species of the common field-vole. Mr. Barrett-Hamilton considered the field-voles of England, Belgium, and the North of France, and possibly of a large part of the continent, as distinct from the Scandinavian animals, which would remain the typical *Microtus agrestis*, while the British and western continental form should be called *Microtus agrestis neglectus*, Jenyns. This view agreed with that of De Selys-Longchamps in 1847.—Mr. F. E. Beddard, F.R.S., read the third of his contributions to the anatomy of Picarian birds. The present paper related to the variations in pterylosis and in anatomy of the *Alcedinidæ*, of which he had examined specimens. Although this family was so uniform in external structure, it presented considerable differences when the pterylosis and anatomy were examined.—Mr. de Winton described a new rodent of the genus *Lophuromys* from British East Africa, which he named *L. ansorgei*.

Royal Meteorological Society, May 20.—Mr. E. Mawley, President, in the chair.—Mr. R. H. Curtis read a paper on the exposure of anemometers, in which he gave the results of a comparison of the records from the three anemometers at Holyhead, viz. the Robinson, the bridled, and the pressure-tube anemometers. It was clearly shown that the force of the wind is greatly affected by surrounding objects. The author is of opinion that for anemometrical records to be trustworthy and of value, not only must the instrument be exposed in an open place, free from local obstructions, but it is also absolutely essential that the stand which carries it shall offer practically no resistance to the wind, and that the instrument should not be placed on the roof of a house. The paper was illustrated by a number of lantern slides.—An interesting collection of photographs of clouds, sent to the Society by Mr. H. C. Russell, F.R.S., of the Sydney Observatory, was also exhibited.

CAMBRIDGE.

Philosophical Society, April 27.—Prof. J. J. Thomson, President, in the chair.—On photographing the whole length of a spectrum at once, by Prof. Liveing. Prof. Liveing exhibited photographs of a variety of spectra in which the whole length of the spectrum between the wave-lengths 550 and 214 was depicted on a celluloid film at one operation. A concave grating of $10\frac{1}{2}$ feet radius was used, with the slit in the centre of curvature, and the slide which held the sensitive film formed part of a cylinder with a radius of $5\frac{1}{4}$ feet, so that, when the axis of this cylinder was midway between the slit and grating, every part of the spectrum was perfectly focused on the film.—On dioxymaleic acid and its derivatives, by Mr. Fenton. This paper contains a brief summary of the author's recent work upon oxidation products of tartaric acid.—(*a*) On the atomic weight of oxygen; (*b*) on the combining volumes of carbon monoxide and oxygen, by Mr. A. Scott. Mr. Scott gave a short account of the present state of our knowledge as to the atomic weight of oxygen, and said that it might be regarded as conclusively proved that if $H = 1$, $O = 15{\cdot}87$ to $15{\cdot}88$. Morley determined the densities of hydrogen and of oxygen, the ratios by volume in which the gases combine (by a somewhat indirect method), and finally combined known weights of hydrogen and weighed the water produced. Thomsen made similar determinations, but with far less pretension to the highest accuracy attainable. The results were:

		Morley.		Thomsen.
Weight of a litre of oxygen at 0° C. and 760 mm. at sea-level, lat. 45°.	...	1·42900	...	1·42906
Ditto for hydrogen	...	·089873	...	·089947
Ratio of densities	...	15·9002	...	15·8878
Ratio of combining volumes	...	1 : 2·00269	...	1 : 2·00237
Atomic weight of oxygen	...	15·879	...	15·869

The ratios by volume in which the gases combine agree well with that published by the author directly three years ago, viz. 1 : 2·00245 at about 15° C., and 1 : 2·00285 at 0° C. Mr. Scott also described some preliminary experiments made to determine the ratio by volume in which carbon monoxide and oxygen unite to form carbon dioxide and to determine at the same time the volume of the latter gas in terms of the others. Experiments so far showed that the ratio was very nearly 2 : 1 for the combining gases, but that satisfactory determinations of the volume of carbon dioxide produced had not been obtained as yet.—On the active principles of Indian hemp, by Messrs. Wood and Easterfield. The authors have examined a sample of charas, the exuded resin of Indian hemp, with a view to isolating the physiologically active constituent. They find that charas contains a compound $C_{18}H_{24}O_2$, B.P. 265°–270° C. at 15 mm. pressure (31 per cent.), to which they attribute the physiological action of the hemp plant. This active compound, which the authors name *Cannabinol*, is a red semi-solid substance at ordinary temperature, but is quite liquid at 60° C.; it yields a monacetyl and monobenzoyl derivative, and can be nitrated. The same compound has been isolated by the authors from the usual medicinal preparations of *Cannabis indica*.—Note on the pharmacological action of hemp resin, by Mr. Marshall. The pharmacologically active compound of charas is the compound, cannabinol. In doses of 0·1 g. to 0·15 g. it produces decided intoxication characterised by fits of uncontrollable laughter, slurring speech, and ataxic gait, a complete loss of time relation, and a sense of extreme happiness: sensation is diminished somewhat, and the pulse-rate rises: as a rule, there are no hallucinations. The acute symptoms last about three hours Smaller doses (0·05 g.) produce similar effects, but to less marked degree. Animals appear to be less susceptible to its influence than man, and herbivorous animals than carnivorous.

PARIS.

Academy of Sciences, May 18.—M. A. Cornu in the chair.—Second note on the theory of gases, by M. J. Bertrand. A critical analysis of Maxwell's second demonstration of the formula giving the distribution of the velocities between the molecules of a gas.—On the *rôle* of the ring of iron in dynamo-electric machines, by M. A. Potier. Remarks on a note by M. Marcel Deprez. The experiment quoted by M. Deprez is only in apparent contradiction to the ordinary rule, the principles involved having been already utilised in the construction of dynamos.—Emission of new radiations by metallic uranium, by M. Henri Becquerel. Metallic uranium gives off invisible rays possessing properties similar to the salts of that metal previously

studied.—Preparation and properties of uranium, by M. H. Moissan.—The significance of an axis of symmetry in plants, by M. A. Chatin.—On the transformation of fat into carbohydrate in unfed animals, by M. A. Chauveau. During hibernation it has been noticed that the animal may increase in weight. This can be accounted for by the partial oxidation of the stearin to glucose, carbon dioxide, and water. If this is really the case the respiratory constant should be about 0·27.—On the integration of the differential equation of the radius vector of a certain group of small planets, by M. O. Backlund.—On a family of left-handed curves, by M. Jules Andrade.—The area of parabolas of higher order, by M. P. H. Schoute.—On some properties of the X-rays penetrating ponderable media, by M. C. Maltézos. A mathematical proof that if the X-rays be regarded as hyper-ultra-violet rays, the different absorptive power of various substances may be explained by supposing that the index of refraction is not exactly unity, but a number very near this value, and depending on the density.—On the application of the formula of Clapyron to the melting point of benzene, by M. R. Demerliac. An experimental study of the lowering of the melting point of benzene by pressure. The manometer used had been calibrated against a mercury column directly, and the alterations in temperature were measured to ·001° by the changes in resistance of an iron wire forming an arm of a Wheatstone's bridge. The alteration in melting point for an additional pressure of one atmosphere calculated from Clapyron's formula is 0°·02936; the experimental figure is ·0294, the difference being less than the errors of observation.—Remarks on the reply of MM. Benoist and Hurmuzescu, by M. Aug. Righi.—Observations on the X-rays, by M. T. Argyropoulos.—On a new ozone generator, by M. G. Seguy.—On a new apparatus for electrolysis, by M. D. Tommasi. In the apparatus described the advantages claimed are the suppression of polarisation, that the deposited metal is removed from the oxidising action of the bath, and that the electrical resistance of the bath is considerably reduced.—Researches on nickel cyanide, by M. Raoul Varet. A thermochemical study of nickel cyanide and its double salts. The thermal data show that the compounds undissociable by dialysis, may be looked upon as salts of a complex acid, hydronickelocyanic acid, differing only from ferrocyanides in stability.—On a crystallised tetrachromite of barium, by M. E. Dufau.—On the chloraloses, by M. Hanriot. Galactose forms a compound with chloral similar to the chloraloses previously prepared. The acetyl and benzoyl derivatives and the acid obtained on oxidising with potassium permanganate are described. The corresponding reactions with levulose were also examined.—On some aromatic symmetrical derivatives of urea, by MM. P. Cazeneuve and Moreau. Carbonate of guiacol serves as the starting point for these compounds, aniline giving diphenyl-urea, paratoluidine, di-paratolyl-urea, and ortho-toluidine, diorthotolyl-urea.—On the ratios which exist between the chemical constitution of organic compounds and their oxidisability under the influence of laccase, by M. G. Bertrand. The degree of oxidation of the aromatic polyphenols studied appears to depend upon the facility with which they can be transformed into quinones.—Characterisation and separation of the chief vegetable acids, by M. L. Lindet. For the separation of citric and malic acids advantage is taken of the different solubility in methyl alcohol of their acid quinine and cinchonine salts.—On the internal appendages of the female genital organs of the Orthoptera, by M. A. Fenard.—On the general relation connecting the degrees of sensation and luminous intensity, and on the laws of simultaneous contrast of lights and tints, by M. C. Henry.—On the browning of the cuttings of the vine, by MM. P. Viala and L. Ravaz—Researches on the carpellary venation in the bicarpellary Gamopetalæ of Bentham and Hooker, by M. Paul Grélot.—On the siphons of springs and underground rivers, by M. E. A. Martel.—The *Cadurcotherium*, by M. Marcellin Boule.—Measurements of the variation in length of glaciers in the French region, by Prince Roland Bonaparte.—Method for defining the position of the surface of emission of the X-rays, by M. Stcherbakof.

BERLIN.

Meteorological Society, April 14.—Prof. Bornstein, President, in the chair.—Dr. Schwalbe spoke on the investigation and most important theories of atmospheric electricity, and added an account of experiments he had made on the dissipation of electricity by vapour. A metal plate insulated, charged to ten volts, and connected with a Thomson's quadrant electrometer, discharged itself in exactly the same time when dry as when wetted with water or other easily vaporised fluid. Sprinkling with finely pulverised quartz greatly hastened the discharge; coarsely powdered glass to a less extent. The time of discharge was the same for a rough as for a polished plate. He considered that these experiments had settled the fact that vapour does not discharge an electrified body, but that fine powders do.

Physical Society, April 17.—Prof. Warburg, President, in the chair.—Prof. König spoke on the number of visual units existing in the human retina. The acuteness of vision was measured by the distance at which a grating made of regular rectilinear wires begins to appear wavy. Starting at the *fovea* it diminishes towards the periphery, and in such a way that the curves of equal visual acuteness form concentric ellipses. The area of each retinal field by which two wires are seen as two, increases towards the periphery. If such a field be called a visual unit, then their total number for the whole retina is 50,000. If it be assumed that each unit can perceive three kinds of colour, of which the resulting impulse is conveyed to the brain by a separate nerve fibre, then there must be 150,000 fibres in the optic nerve. As a matter of fact, histologists give them as 400,000 to 500,000 in number. He further discussed the experiments he had made in conjunction with Dr. Zumpf, which had shown that objects of different colour must be perceived at different depths in the retina. The difference of these depths for red and blue rays was found to be so great, that one lay in the pigment layer, which must hence be regarded as a sensory organ. As a matter of fact, quite recently an English anatomist has described the existence of spherules in this layer united to a nerve-plexus from the rods and cones. He finally gave an historical retrospect of Purkinje's phenomenon, in which two coloured (red and blue) fields of equal luminosity as seen by daylight appear unequally luminous at twilight, the red disappearing much sooner than the blue. After this phenomenon had been studied by a whole series of observers, and its importance insisted upon, Prof. Hering had quite recently found that it is really an exceptional phenomenon. It can only be observed in dark surroundings; in daylight and bright surroundings the differently coloured fields remain equally luminous, while the intensity of their illumination is reduced down to a point at which colour perception ceases. Prof. König had satisfied himself of the truth of the above observation, so that Purkinje's phenomenon has now lost all its supposed significance.

May 1.—Prof. von Bezold in the chair.—Dr. du Bois spoke on the magnetising and hysteresis of various kinds of steel and iron, basing his remarks on experiments made in conjunction with Mr. E. T. Jones. The discrimination of different samples of iron by means of their hardness has now lost all its importance; the real criterion is rather hysteresis, coercitive power, residual and maximal magnetisation, which had been determined, together with other magnetic properties, for a large series of samples. Chemical composition is of less importance than the mode of treatment during manufacture from ore to metal. The magnetic constants of the material are of importance to physicists and technologists. The speaker then gave the results of his measurements for three kinds of iron with maximal, and three with minimal hysteresis. As a general rule hardening increases hysteresis and coercitive intensity, whereas residual magnetism is lessened. Krupp's cast-iron is distinguished by its low hysteresis and small coercitive intensity.

PHILADELPHIA.

Academy of Natural Sciences, April 14.—In connection with the presentation of a collection of recent and fossil Strombidæ, Mr. H. A. Pilsbury discussed the ancestry of *Strombus costata* and *Melongena subcoronata*, their relations fossil species being illustrated by large suites of intermediate forms.—Mr. James Willcox commented on the influence of environment on the species as illustrated by the specimens presented. It was apparent that those from the southern coasts of Florida swept by the Gulf Stream were all of a dwarfed type.—Dr. Benjamin Sharp related the plentiful occurence of a Ctenophore, *Mneopsis Leidyi* in a fresh-water pond near Nantucket. The embryos had been swept in by an accession of salt water, and had accustomed themselves to their new environment. The species did not, however, persist in the pond, in consequence probably of the severity of the winter. Specimens of the species referred to were beautifully preserved in a 2 per cent. solution of formaline.—Mr. Pilsbury announced the finding by Mr.

Charles Johnson, for the first time in the Eocence of Texas, of a representative of the genus Scalpellum. It is a new species for which the name Chamberlaini was proposed, in recognition of the services of the Rev. L. T. Chamberlain to palæontological science.

NEW SOUTH WALES.

Linnean Society, March 25.—The President, Mr. Henry Deane, in the chair.—The President delivered the annual address, in the course of which the subject of forestry, especially in relation to the needs and resources of Australia, was brought forward, and the experiments of other countries were summarised, as a safe guide to be followed. The question of the origin of the Australian flora was also dealt with at some length, critical objections being offered to Ettingshausen's views on the characters of the Australian Tertiary flora, based upon no more satisfactory evidence than is afforded by leaf-remains. The address concluded with a summary of the salient points of interest in the recently issued first instalment of the "Report of the Horn Expedition to Central Australia" (Zoology, part ii., edited by Prof. Baldwin Spencer), a work which, in its completed form, promises to be the most comprehensive and elaborate account of the natural history of any portion of the continent ever issued in a self-contained form.—The following papers were read:—A contribution to the structure and relations of the organ of Jacobson in the horse, by Dr. R. Broom.—Descriptions of further highly ornate boomerangs from New South Wales and Queensland, by R. E. Etheridge, jun.—Note on the occurrence of callosities in *Cypræa* other than *C. bicallosa* and *C. rhinocerus*: and on the presence of a sulcus in *Trivia australis*, by Agnes F. Kenyon.—On a new genus and species of Australian fishes, by J. D. Ogilby. The genus *Apogonops* is proposed for a small fish of puzzling affinities from Maroubra Bay. At a first glance it would seem to be naturally referable to the family *Apogonidæ*. But this view is precluded by the absence of vomerine teeth and the number of its dorsal spines, unless it is to be considered as an aberrant Apogonid with sciænoid affinities.—Catalogue of the described Coleoptera of Australia. Supplement. Part ii. *Dytiscidæ* and *Staphylinidæ*, by George Masters.

GÖTTINGEN.

Royal Academy of Sciences.—The *Nachrichten* (mathematico-physical series) part 1 for 1896 contains the following memoirs contributed to the Society.

January 11.—Pendulum observations at Freden and Alfeld, by A. von Koenen.—The movement of the spinning-top, by F. Klein.

January 25.—Discovery of *Ceratites nodosus aut.* in the Vicentine Trias, and its stratigraphical significance. A new demonstration of Kronecker's fundamental theorem on Abelian *Zahlenkörper*. A letter of Gauss to Gerling (on Bolyai's geometry), by Paul Stäckel. Continuous groups of quadratic transformations of the plane, by G. Bohlmann.—On the representation of finite groups by means of Cayley's colour-diagrams.

February 8.—Researches conducted in the Göttingen University laboratory (III.), by O. Wallach. (1) A new heptylamine. (2) Ketones from propenyl-compounds. (3) On reuniol. (4) On pinol hydrate. (5) On isothujone and thujamenthone. (6) Refractive and dispersive powers of a series of isomeric camphors.

March 7.—The theory of the formation of petroleum, by Fr. Heusler.—On a theorem in the analysis of position, by A. Schoenflies.

AMSTERDAM.

Royal Academy of Sciences, April 18.—Prof. Van de Sande Bakhuyzen in the chair.—On four-dimensional prismoids, by Prof. Schoute.—On the equilibrium of radiation in the case of doubly-refracting bodies, by Prof. Lorentz.—Prof. Kamerlingh Onnes presented a paper to be published in the report of of the meeting, and entitled "a contrivance for lighting up scales for mirror-reading," and also, on behalf of Dr. L. H. Siertsema, a communication on measurements of the magnetic rotation of gases. This communication is a continuation of those published in the *Transactions*, 1893–94, p. 31, and 1894–95, p. 230. After supplementing the descriptions of the apparatus, the method of observation, and the manner of calculation—a plate being added for illustration—the author communicated the results with respect to air, oxygen, nitrogen, carbonic acid, and nitrogen monoxide. The results for the first two gases have been deduced from the same observations as the previous ones, but have been re-calculated, a better determination of certain constants having been obtained. Moreover, the rotations have been expressed in minutes, by means of a provisional reduction factor. The results for CO_2 and N_2O must only be considered as provisional, as the pressure was not measured with sufficient accuracy.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—The Alternate Current Transformer: Dr. J. A. Fleming, Vol. 1, new edition (*Electrician* Company).—Physics for Students of Medicine: Dr. A. Daniell (Macmillan).—The Flora of Dumfriesshire: G. F. Scott-Elliot (Dumfries, Maxwell).—Through Jungle and Desert: W. A. Chanler (Macmillan).—The Frog: Prof. A. Milnes Marshall, 6th edition, edited by Dr. G. H. Fowler (Nutt).—The Great Rift Valley: Dr. J. W. Gregory (Murray).—A Manual of North American Birds: R. Ridgway, 2nd edition (Lippincott).—Fur and Feather Series. The Hare: Macpherson, &c. (Longmans)—Press-Working of Metals: O. Smith (Chapman).—Mars: P. Lowell (Longmans).—How Plants Live and Work: E. Hughes-Gibb (Griffin).—Official Year-Book of the Scientific and Learned Societies of Great Britain and Ireland, 13th annual issue (Griffin).—Reminiscences of a Yorkshire Naturalist: Prof. W. C. Williamson (Redway).—Miscellaneous Papers: Prof. H. Hertz, translated by D. E. Jones and G. A. Schott (Macmillan).—A System of Medicine: edited by Prof. T. C. Allbutt, Vol. 1 (Macmillan).—Catalogue of the Madreporarian Corals in the British Museum (Natural History), Vol. 2: H. M. Bernard (London).—Catalogue of the Snakes in the British Museum (Natural History), Vol. 3: G. A. Boulenger (London).—Lehrbuch der Ökologischen Pflanzengeographie: Dr. E Warming, Deutsche vom Verfasser Genehmigte Durchgeschene und Vermehrte ausgabe: Dr. E. Knoblauch (Berlin, G. Borntraeger).—The Indian Calendar: R. Sewell and S. B. Dikshit (Sonnenschein).—Results of Rain, River, and Evaporation Observations made in New South Wales, 1894 (Sydney).

PAMPHLETS.—Die Grenzen Geistiger Gesundheit und Krankheit: Dr. P. Flechsig (Leipzig, Veit).—Thoughts on Evolution: P. G. F. (Sonnenschein).

SERIALS.—Quarterly Journal of Microscopical Science, May (Churchill).—Bulletins de la Société D'Anthropologie de Paris, 1895, No. 6 (Paris, Masson).—Mémoires de la Société D'Anthropologie de Paris, tome 1, 3e série, 4e Fasc. (Paris, Masson)—Journal of the Institution of Electrical Engineers, May (Spon).—Quarterly Journal of the Geological Society, May (Longmans).—Natural Science, June (Rait).—Longman's Magazine, June (Longmans).—Himmel und Erde, May (Berlin).—Illustrations of the Zoology of H.M. Indian Marine Surveying Steamer *Investigator*, 5 parts (Calcutta).—Good Words, June (Isbister).—Sunday Magazine, June (Isbister).

CONTENTS.

THURSDAY, JUNE 4, 1896.

TWO BOOKS ON ELECTRICITY AND MAGNETISM.

Elements of the Mathematical Theory of Electricity and Magnetism. By J. J. Thomson, M.A., F.R.S., Fellow of Trinity College, Cambridge, and Cavendish Professor of Experimental Physics in the University of Cambridge. Pp. vi + 510. (The Cambridge University Press, 1895.)

Elementary Treatise on Electricity and Magnetism, founded on Joubert's "Traité Élémentaire d'Électricité." By G. C. Foster, F.R.S., Quain Professor of Physics in University College, London; and E. Atkinson, Ph.D., formerly Professor of Experimental Science in the Staff College. Pp. xix + 552. (London: Longmans, Green, and Co., 1896.)

PROF. THOMSON'S book will do good in many ways. Even its title will correct a wrong impression which very generally prevails, to the effect that just so much of the fundamentals and facts of the subject as can be discussed with the aid of a smattering of geometry and algebra, constitutes the truly elementary theory of electricity. On the contrary, students will find that the phrase *Elements of Electricity and Magnetism* really means that satisfactory grounding in essential ideas and their relations which is only possible to a student whose mathematical education has been or is being made adequate to the study of the higher parts of electricity. No important part of the subject is omitted, and of course this brings into play here and there mathematical processes more recondite than some which many practical men seem to shrink from. But there is no obtrusion of purely mathematical discussion; the analysis arises just where it is wanted, to the extent to which it is wanted, and goes no further.

A feature of the book which strikes the reader at once is the use made of the idea of Faraday tubes of force, or rather of electric induction in a dielectric. The distribution of these in the field in different cases of electrification is very fully described and illustrated graphically. This is a matter of very great importance. The examination of students supposed to have received a sound training in elementary electricity has convinced us that very few have a really clear notion of the actual nature of the electrification of a conductor in presence of external and internal charges. Of the dependence on the internal system of charges of the amount and distribution of the charge on the interior surface, and of the nature of the effect of the external system on the distribution on the exterior surface, they seem frequently to have no notion whatever, though they talk glibly about Faraday's ice-pail experiment and his "living" within the large tin-foil covered cube he made and electrified.

A very good elementary account is given of the subject of electric images, and several important particular cases are discussed; for example, that of two unequal spheres intersecting at right angles. This is then converted into the useful problem of the effect of a small hemispherical boss on the capacity of a large sphere.

The effect of dielectrics in the field is then considered the method of electrical inversion introduced, and the usual problems of mutually influencing spherical surfaces solved. An excellent characteristic of this part of the book, as indeed of the work as a whole, is the working out of clearly formulated expressions which, on insertion of the proper numerical data, give at once the absolute values of important electrical quantities.

What we have said as to the clearness of the discussion of electrostatic theory applies also to the treatment of magnetism and the steady flow of electric currents. The treatment of electrolysis strikes one as rather meagre, but all the statements made are concise and to the point. The table of electrochemical equivalents on p. 282 stands in need of revision, the decimal point seems misplaced in one or two of the numbers.

In the discussion of the magnetic action of currents, Prof. Thomson applies elementary methods successfully to the determination of the magnetic fields of simple systems of currents, and might possibly have gone further in the same direction. But this chapter, the long one which follows on electromagnetic induction, and the thirteenth, which treats of dielectric currents and the electromagnetic theory of light, are the most interesting and important in the book. The first two of these deal with the phenomena and their quantitative expression, the last discusses the production of a magnetic field by the motion of Faraday tubes, Maxwell's theory of the propagation of electromagnetic disturbances, and the verification of this theory by experiment. To show the extent and thoroughness of the discussion, we may mention that the concentration of a rapidly alternating current near the surface of a conductor is explained by general considerations derived from the flow of heat, and, what is still better, is illustrated quantitatively by the case, which is fully worked out, of alternating currents induced in an infinite mass of conducting material bounded by a single plane face, beyond which in the insulating medium the inducing system is situated. This leads to a comparison of the distances to which currents sensibly penetrate in different metals, such as copper and iron, which lie widely apart as regards magnetic permeability.

An account, necessarily of course very short, but good so far it goes, is also given in the chapter on the "Dimensions of Electrical Quantities," of the absolute determination of resistance and the comparison of units. The method of the revolving coil and that of Lorenz are all that are described in the former case, and Maxwell's bridge method (employed so successfully by Prof. Thomson himself in conjunction with Mr. Searle) of finding in electromagnetic units the capacity of a condenser, and thus finding a number for comparison with the electrostatic value, is alone given in the latter case.

Here as elsewhere the author does not shrink from the introduction of a differential equation and its solution. The only alternative is the insertion of the result without proof. The inclusion of the necessary analysis, if it can be done without undue prolixity, is not, as it frequently seems to be regarded, an introduction of "useless mathematics." The justification of the result ought always to be indicated. If the reader cannot understand the proof, he can pass it over; its presence may serve to remind him that besides the mere results there is something

more to be apprehended and appreciated—the theory by which they have been obtained.

In the chapter on the "Dimensions of Electrical Quantities," the author introduces besides μ and K a third constant p, which may arise in connection with the relation between the current and the magnetic intensity at any point in the field produced, so that 4π times the current flowing through a closed path in a magnetic field is equal to p times the work done in carrying a unit pole once round the path. The dimensions of this constant are of course unknown, and it is only by assuming its dimensions to be zero that the ordinary dimensions of current in electromagnetic units are obtained. There does not seem any distinctly physical ground for bringing in this constant p. The work done in carrying a pole in a complete circuit round a current is independent of the nature of the medium, and hence, justifiably so far as we can see, it may be taken as unity, without involving any neglect of the physical properties of the medium.

The method of the motion of Faraday tubes of electric induction is used in the chapter on "Dielectric Currents and the Electromagnetic Theory of Light." Perhaps it is possible to make too much of this conception; but there can be no question of its great utility as a means of keeping before the mind of the reader the idea of electric and magnetic action as taking place in the medium, and visualising, as it were, what takes place when a condenser is joined to another and partially discharged, when a current flows in a circuit, and the flux of energy in the medium which accompanies all such changes, whether constant or rapidly variable.

The commendation which the work of Prof. J. J. Thomson thoroughly deserves is the due also of that which Prof. Carey Foster and Dr. Atkinson have based on the elementary treatise of M. Joubert. This work has been recast so as to bring it thoroughly into accordance with the later views of electrical theory, and there can be no question of the entire success with which the English authors have performed their task. The book is a thoroughly sound and practical treatise. In it too, though not to the same extent, for its aim is different in some degree, there is a good deal of fairly advanced theory, and like the former work, it shows no shirking or glossing over of difficulties. It contains a more detailed account of the experimental details of the subject than the other work, and this, by the use of a somewhat small but still perfectly clear type, is got in without unduly swelling the volume. The two books read together would form an excellent combination. They are enough to give any competent student a most desirable acquaintance with the essential parts of the main phenomena, and their elementary theory. Such a student would afterwards go easily and rapidly forward with the study of the more elaborate theoretical works, and of the researches which have lately advanced electricity so much—the absolute determinations of electrical constants which have been made by so many experimenters, and the improved science of electrical measurement which these, together with the experimental investigation of the electromagnetic theory of light, and the vast development of practical electricity, have brought into existence.

A. GRAY.

ANNALS OF THE CALCUTTA BOTANIC GARDEN.

Annals of the Royal Botanic Garden, Calcutta. Vol. v. Part I. Pp. 9 + 68, 101 plates. (Calcutta: the Bengal Secretariat Press, 1895.

THE Royal Botanic Garden, Calcutta, has been publishing from time to time a series of "Annals," illustrative of the flora of the continent of India, the adjacent islands, and the contiguous countries. Volume v. of this work was published last year, and Part 1 consists of "A Century of Indian Orchids" by the chief of contemporary botanists, Sir Joseph Hooker. The Calcutta Garden has had the advantage of the services and labours of a long series of eminent botanists. Volume v. of the "Annals" is dedicated to perhaps the most distinguished of them, Roxburgh, superintendent from 1793 to 1814, and author of the "Plants of the Coromandel," the "Hortus Bengalensis," and the "Flora Indica," of whom a portrait and a brief memoir are prefixed. It may be well to recall the names of Roxburgh's successors to show how well botany has been served in connection with these gardens. They have been Wallich, Falconer, Thomson, Anderson, Clarke, and King; the last named, an admirable administrator and a distinguished botanist, being still in charge.

Since Roxburgh's time, that is for more than a century, what Sir Joseph Hooker describes as a "magnificent series of Indian plant-portraits by native artists" has been accumulating in the Calcutta Botanic Garden, of which about a thousand are those of orchids.

"The most important of these collections," says Sir Joseph ("Flora of British India," vol. v. p. 176) "were Malayan, abounding in novelties from Penang, Perak, Singapore and Malacca, made by the late Father Scortechini, . . . by Kunstler (a collector sent from the Calcutta Botanical Gardens by Dr. King), by Curtis Hullett, Wray and Ridley. Important collections were also sent by Mann from Assam, Bhotan, and the Khasia Hills; by Gamble from various parts of India; by Duthie from Garwhal; by Clarke from Sikkim, the Khasia Hills, and Bengal, together with a few from Central India; and by Dr. Trimen from Ceylon."

So little accessible were these drawings, and so little was their value known, that it was not until Sir Joseph Hooker had almost completed, as he mentions in his brief preface to the "Century," the descriptions of Indian orchids for his monumental work, the "Flora of British India," that he obtained, through Dr. King, the loan of the native drawings referred to. Sir Joseph further states that "the inspection of these drawings," coupled with the study of other material received from Calcutta, "necessitated a revision of the characters of the greater portion of the species already described, . . . together with the addition of not a few new species."

With reference to these drawings, the author states that, excellent as they are in many respects, they betray "that tendency to enlarge, which is the besetting sin of Indian botanical artists." Perhaps it is rather the indifference to exact accuracy—a strongly-marked characteristic of all Indian artists—which is in fault. No one who has had to do with Indian workmen can have failed to notice how difficult it is to induce them to recognise the importance of accurate measurements and proportions.

Now that so much attention is devoted to orchids in the gardens of Great Britain, and that their cultivation is, comparatively speaking, well understood, the publication of such a volume as the "Century" by our great botanist is a valuable help, not only to botanists, but to gardeners. Although all accessible parts of India have been searched through and through by experienced collectors, it is nevertheless a fact that comparatively few of the plants comprised in the "Century" are known to be in cultivation. Take, for example, the beautiful genus *Dendrobium*, of which so many charming species adorn orchid houses. Eighteen species of the genus are figured and described in the "Century," of which but one is to be found in Veitch's "Manual of Orchidaceous Plants," the best and most complete book on the subject. Even in the recently published "Hand-List of Orchids cultivated in the Royal Gardens" at Kew, there are mentioned but four out of the eighteen. There is an unfortunate tendency among orchid growers to view with scant favour the vast number of beautiful, delicate and interesting *small* orchids. An examination of the plates in the "Century"—which, by the by, are somewhat coarsely coloured—must prove that there are numerous genera and species well worth care and cultivation, even though they may not be as showy as a *Cattleya* or an *Odontoglossum*

Among the more striking of the plants figured in the "Century" are *Dendrobium crocatum* (Hook. f.), with its brilliant orange-coloured flowers; *D. Williamsoni* (Reichb. f.); *D. leonis* (Reichb. f.), with its remarkable imbricated leaves, and exquisite scent of vanille; *Cirrhopetalum gamosepalum* (Griff.); *C. refractum* (Zoll; and *Eria obesa* (Lindl.), with its clusters of spindle-shaped bulbs. Among others the following would be valuable additions to collections from a horticultural point of view—viz. *Acanthephippium striatum* (Lindl.); *Phaius Mishmeensis* (Reichb. f.); *Calanthe herbacea* (Lindl.), a very handsome plant growing in the Sikkim Himalayas, at an altitude of from 4000 to 6000 feet; *Eulophia* (*Cyrtopera*) *nuda* (Lindl.), figured in four varieties, of which the variety *purpurea* is the most distinct; *Eulophia* (*Cyrtopera*) *macrobulbon* (Hook.); *Sarcanthus insectifer* (Reichb. f.), a remarkable and exceptionally bright-coloured species from the Chittagong Hills; and several fine species of the genus *Habenaria*.

As the botanical descriptions in this work are from the pen of Sir Joseph Hooker, it would be presumptuous to praise them. Notes are appended to nearly every description, giving the habitat of the plant, the height above the sea at which it was found, the name of the discoverer where known, and other particulars.

As few of these beautiful and interesting orchids are even mentioned in manuals and lists of cultivated orchids, there is evidently still a wide field for orchid collectors, even in easily accessible parts of the British Empire and the neighbouring countries. And who knows but that the zeal of some collector working in the country north of the Bay of Bengal, might be rewarded at any moment by a re-discovery of that rare gem among slipper orchids, *C. Fairrieanum*! There has been but one importation, in 1857, of this elegant and graceful plant. "Its blossoms," says the late Sir William Hooker, "are certainly among the most exquisitely coloured and pencilled of any in this fine genus." It comes from Assam or Bhotan, countries well within reach; but probably has a very restricted habitat, and a station remote and difficult of access. Still the commercial value of an importation would be so great, that the zeal of importers and collectors ought not to cool until success crowns their efforts. The recent re-discovery of the habitat of the true *Cattleya labiata* (*autumnalis*), found by Swainson in 1818 on the Organ Mountains in Brazil, and lost sight of for over seventy years, is a case in point. May a like happy chance occur in the case of *Cypripedium Fairrieanum*! T. L.

OUR MINERAL INDUSTRIES.

First Annual General Report upon the Mineral Industry of the United Kingdom of Great Britain and Ireland for the year 1894. By C. Le Neve Foster, D.Sc., F.R.S. Pp. 144. Seventeen plates. (London: Printed for Her Majesty's Stationery Office, 1895.)

EVER since the year 1853 the position of the mineral industries of this country has been regularly recorded in an official volume, issued annually under the title of "Mineral Statistics of the United Kingdom." A series of these annuals, extending over nearly thirty years, was prepared under the direction of the late Mr. Robert Hunt, and issued from the Mining Record Office in Jermyn Street. For several years, however, two sets of returns were published concurrently—one set by Mr. Hunt, whose figures were obtained by the voluntary aid of mine-owners, and another set by the Inspectors of Mines, whose statistics were based upon statutory returns, and, consequently, came to be regarded as more trustworthy. To avoid the inconvenience of such duplication, the work of the Mining Record Office was taken over, in 1882, by the Home Office; and thenceforth there issued annually from this department a statistical volume as well as the ordinary Reports of the several Inspectors of Mines. These two publications have hitherto been the only official sources of information on mining published in this country. But something more was evidently wanted—something rather in the shape of a general year-book of mines and minerals. The publication of a comprehensive report of this character was suggested by the Royal Commission on Mining Royalties, and the suggestion was endorsed by the Departmental Committee on Mining and Mineral Statistics. At the request of the Home Secretary, Prof. Le Neve Foster undertook the preparation of such a report; and, considering the initial difficulties incidental to an undertaking of this kind, he is to be heartily congratulated on the work which he has produced.

After an introductory essay, explanatory of the various laws which regulate the working of minerals in this country, Prof. Foster deals with the statistics of the mining population. It appears that the number of persons employed underground in our mines during the year 1894 was 589,689, whilst those working in connection with surface-operations numbered 149,408; thus giving a total mining population of 739,097. The distribution of the underground workers in the various counties is represented on a coloured map, which shows at a glance that Durham and Glamorgan are the two counties with the

largest number of miners. At the same time it must be remembered that, as the miners are not spread uniformly over any of the counties, the actual density of the mining population can never be accurately shown on such a map.

The total value of the minerals raised in each county is approximately indicated on another coloured map; and there are also maps showing the output, according to counties, of coal, iron-ores, lead-ores, and zinc-ores. The statistical maps and diagrams, which add greatly to the value of the Report, have been prepared mainly, we believe, by Mr. J. B. Jordan, whose experience in dealing with mineral statistics has extended over nearly forty years.

Among the diagrams is one showing graphically the annual output of coal and the quantity exported from 1860 to 1894, whilst a similar diagram shows the iron ore raised and the quantity imported for the same period. The annual production of the ores of copper, lead, tin and zinc, during a like period of thirty-four years, is also illustrated by special diagrams. Perhaps the most interesting of all the diagrammatic schemes are those dealing with accidents in mines. These tabular returns, extending from 1851 to 1894, suggest very melancholy reflections, but still it is matter of satisfaction to note that, on the whole, the miner's lot has been ameliorated. Prof. Foster, referring to a table of death-rates, points out that "mining has immensely improved in safety during the last forty-four years. The mortality from accidents has dropped and goes on dropping. From time to time disastrous explosions have caused a temporary rise, but on the whole there is firm and steady progress in the right direction" (p. 36).

Some two or three years ago a great improvement was effected in the "Mineral Statistics" by the introduction of brief descriptive notices respecting the mode of occurrence of the several minerals referred to in the returns. It is understood that these remarks were from the pen of Prof. Foster, and he has very properly reproduced them in this Report. So far as they go, they are models of concise description; but it is to be hoped that opportunity may be found, in some future work, for their amplification, for at present they rather whet the appetite than afford it full satisfaction.

A comparison of the mineral industries of this country with those of other lands, forming Part vi. of the General Report, must have involved an immense amount of labour, inasmuch as it necessitated the collecting and collating of the mineral statistics of the world. The statistical returns are accompanied by valuable descriptive remarks on the resources of each country; and with such thoroughness has this part of the work been done, that Prof. Foster adds notes in connection with countries, like Arabia, Egypt and Turkey, whence little or no statistical information can be procured. There are necessarily many gaps in the foreign statistics; but steps have been taken to secure fuller returns in future, and the subsequent reports will probably be less imperfect. Prof. Foster has prepared a form, in English and French, asking for specific data, and copies of this form have been issued, through the Colonial and Foreign Offices, to Her Majesty's representatives abroad.

Notwithstanding the care bestowed upon the preparation of the Report, and the evident desire to bring its information up to date, it still necessarily falls short, in some respects, of an ideal report on our mineral industries. The information, for instance, respecting stone obtained from quarries is only meagre; but the Quarries Act of 1894 will enable us in future to have statutory returns from all open workings, more than twenty feet deep. If the aid of a staff of specialists could be secured, the descriptive part of the Report might be advantageously expanded, and a volume produced something like that on the Mineral Resources of the United States, issued annually by the Geological Survey, or like the admirable work started a few years ago in New York by Mr. Rothwell. Even, however, in its present form, Prof. Foster's Report presents us with a record of the mineral industries of our country, far more comprehensive, instructive and accurate than anything which the British miner has hitherto possessed.

OUR BOOK SHELF.

Leerboek der Organische Chemie. By Dr. A. F. Holleman. (Groningen: J. B. Wolters, 1896.)

The author in his preface says that text-books of organic chemistry, used in Holland by students of medicine and pharmacy and by candidates in the faculty of science, contain too much and too little—too many facts and too little theory.

There is no doubt that this criticism of our larger organic text-books is a fair one. Volumes like those of Richter and Bernthsen are distended with an unnecessary number of compounds, whilst they conceal within an occasional paragraph of small print important questions of theory; they are books for reference rather than for study. In the present case the author wisely attempts to minimise the number of compounds, and boldly discusses in full-sized type points of theoretical interest as they present themselves. The influence of the Amsterdam school of chemistry is very apparent in this.

We find accounts of geometrical isomerism, including Hantzsch and Bamberger's latest views on the constitution of diazo-compounds, of the relation between osmotic pressure and the freezing and boiling point of solutions, of Arrhenius' electrolytic dissociation theory and its application to the determination of the strength of acids, of the thermodynamic law, which underlies the conversion of racemates into tartrates, &c., all clearly and concisely given.

There can be little objection to physical-chemical theories entering into the composition of an organic text-book; they are interesting and suggestive. But the author has unfortunately fallen into the error of neglecting the practical side of the subject, of too frequently ignoring the laboratory and the works, of omitting experimental details of important preparations, and of presenting to the student chemical reactions as a series of ingeniously contrived equations.

We do not know, of course, for what type of student the book is intended; but it would be out of the question to put it into the hands of a beginner, or of one who had had no previous training in practical organic chemistry.

J. B. Cohen.

Physics for Students of Medicine. By Alfred Daniell, M.A., LL.B., D.Sc., F.R.S.E. Pp. 469. (London: Macmillan and Co., Ltd., 1896.)

Dr. Daniell's "Principles of Physics" is known to be an excellent systematic treatise on physical science, setting forth fundamental principles in a sound and scientific way. In the volume now under notice the same orderly arrangement is followed as in its larger

forerunner, the result being that the book provides a good general preparatory course, which will give students of medicine a broad and satisfactory view of the principles of physics, and will equip them with very serviceable knowledge. Intended primarily to meet the new regulations of the General Medical Council (which make physics a part of the extended course of professional study), the book contains numerous examples of the application of physical principles to medical science, relating both to instruments and muscular actions. But though medical students will find special interest in some of the examples used to illustrate the subjects described, the information given can readily be understood by all who read with studious mind. Therefore we commend Dr. Daniell's volume to teachers of physics generally, believing that they will find it worthy of adoption. The contents include chapters on units of measurement, motion of bodies, friction, matter, sound, heat, ether-waves, and electricity. All these subjects are treated as thoroughly as is possible in a book of this character.

Physics cannot be learned; it must be experienced. Dr. Daniell recognises this, and points out that his work "is not designed to supersede, but rather to clear the ground for practical teaching and demonstration." It is to be hoped that this practical work will some day form a part of the professional curriculum.

Physical Units. By Magnus Maclean, M.A., D.Sc., F.R.S.E. Pp. 147. (London: Biggs and Co., 1896.)

IT can safely be said that this book will find its way into every laboratory where physical facts are investigated. The tables of results brought together in the volume will be most useful for reference; and as they represent determinations made by foremost workers, trust can be put in them. Additional value is given to the tables by the fact that references are made in most cases to the books and papers from which the data have been obtained.

Two-thirds of the book are devoted to the discussion of physical units and the relations between them, the remaining third being taken up with the tables already mentioned. Students of physics will obtain from the text clear and sound knowledge of their units of measurement, and to more advanced investigators the book will prove a veritable vade-mecum.

Elements of the Theory of Functions. By Dr. H. Durége. Translated by George Egbert Fischer and Isaac J. Schwatt. Pp. 288. (Philadelphia, 1896.)

THE late Prof. Durége's treatise, in this English translation, will be a welcome addition to the works on this subject by Forsyth and Harkness and Morley. Durége has a genial method of exposition, as all who know his other book on Elliptic Functions will testify. The numerous definitions and novel ideas in the "Theory of Functions" are made clear by well-chosen illustrations and diagrams. There is no reference to the date of the first edition, but we believe it goes back some thirty years; so that Durége could claim to be a pioneer in the presentation of this subject to the general reader, Weierstrass's ideas being inaccessible to all except his own university pupils. G.

Charles Darwin and his Theory. By M. A. Antonovich. Pp. 353, with a portrait. (Russian.) (St. Petersburg, 1896.)

THIS is a very good summary of the chief works of Darwin, in which his scientific views are intimately interwoven with personal details of his life, in so far as they are known from Francis Darwin's "Life and Letters," and partly from Krause's "Charles Darwin," the whole being written with a deep admiration of both Darwin's personal qualities and his philosophy.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Query concerning the Origin of Atolls.

HAVING recently visited and studied in some detail the coral mass of the Bermuda Islands, I have been impressed by one thing more than by anything else, namely, the fact so long known that the islands owe their present elevation almost exclusively to the action of the wind. The hills, which often rise to a height of 200–250 feet above the sea, from near their base to their summit, are made of blown coral sand, now consolidated into a more or less compact rock.

A recent subsidence has carried most of the islands below the sea level, leaving only the more elevated southern part above, because this had been built higher than the rest by the strong southern winds. This subsidence has been so recent that the heavy south waves are still battering at the cliff; and the débris thus obtained, added to that furnished by the abundant coral growth of the reef which lies immediately off shore, has not yet been able to build extensive beaches. Here and there we find beaches, usually small ones, and from these the sand is even now marching inland and adding to the height of the land, illustrating the process by which the islands have been reared to their present height. Nevertheless, although in a few places the importance of the wind action is still illustrated, it is practically at an end, and that because of a recent subsidence of certainly 50 feet and probably less than 100 feet.

On the basis of these facts I wish to propound a query which has arisen in my mind, but which I would not assume to answer on the basis of a study of only one coral island. Granting an atoll ring formed in the mid-ocean in the way which the theory supported by Dr. Murray and others demands, would we not of necessity have first a ring of reef or beach rock, then of coral sand which with age continued to rise in elevation until the Bermuda stage was reached? For various reasons a luxuriant vegetation would not at first serve to check this. A constant supply of sand is furnished by the life which skirts the shore, the waves are present to drive it on the shore, and the wind to heap it up.

Given this tendency and islands either standing at a uniform level, or being elevated, there should, it would seem, be all gradations between the atoll ring and the insular mass of wind-blown sand not unlike the Bermudas. If, however, the older theory advocated by Darwin and by Dana were correct, there would not need to be such a condition, for subsidence would counteract the action of waves and winds, and the ring condition of the low atoll could easily be the type condition.

Cornell University, Ithaca, N. Y. RALPH S. TARR.

"The Primary Factors of Organic Evolution."

IN a review of Prof. Cope's "Primary Factors of Organic Evolution" (NATURE, vol. liii. p. 553), Dr. Alfred R. Wallace denounces its "extraordinary statements," its "misstatements," and its "absurd arguments," and finds it refreshing to turn to the original ideas and acute reasoning of another book. The fact that the first book is by an opponent and the second by a follower of the reviewer, perhaps accounts for, though it does not justify, opinions that depart widely from what will be the judgment of the most competent. A work of unusual originality such as Prof Cope's, is apt to contain much that is open to criticism; but it is no small matter to have brought together, as he has done, the evidence in favour of finding in the environment, in the movements of animals and in consciousness, the efficient factors of organic evolution. The present writer finds the arguments inconclusive, but he does not understand how any one can read the book without admiring the intimate knowledge of facts and the great powers of generalisation which it discloses. Dr. Wallace states that it is "absolutely untrue" that "the variation which has resulted in evolution has not been multifarious or promiscuous, but in definite directions," yet the evidence offered for this proposition—due perhaps more to Prof. Cope than to any other—has within the past few months proved convincing even to Prof. Weismann. Prof. Cope's book and his work should be adequately described and seriously criticised; but Dr. Wallace has done neither. J. MCKEEN CATTELL.

Columbia University, New York, May 9.

Barisal Guns.

IN reference to Sir Edward Fry's letter in NATURE for May 7, a fuller account of the mysterious sounds heard at Jebel Musa, and Jebel Nagus, in the Peninsula of Sinai, will be found in Palmer's "Desert of the Exodus," vol. i. pp. 217, 251. The former, which an Arab legend attributes to a fairy maiden, who fires off a gun one day in every year to give notice of her presence, "are," says the writer, "in all probability caused by masses of rock becoming detached by the action of frost, and rolling with a mighty crash over the precipice" (of 3000 feet) "into the valley below." The sounds at Jebel Nagus, which have also a legend connected with them, are undoubtedly due to the friction of rolling sand. From experiments made by the explorers, the degree of coarseness of the sand, the angle of inclination of the slope, and temperature, seem to be the controlling conditions.

Hampstead, N.W.

THE SPERM WHALE AND ITS FOOD.

OUR fund of accurate knowledge of the Cetacea being at so low a level, it is to be deplored that trained scientific observers have hitherto had few opportunities for noting under normal conditions the habits of these most interesting animals. And therefore naturalists generally will certainly hail with delight the news of the resolution of the Prince of Monaco to endeavour by all the means at his disposal to make an effective study of that least understood of all the deep sea mammalia—the great sperm whale. An observer like Dr. Scoresby who, while gaining his livelihood by the pursuit of the Greenland whale, lost no opportunity of studying that monster's manners and customs for the benefit of science generally, is still to seek for the world-wide fishery of the cachalot. This may be said without in the least minimising the excellent work done by Surgeons Beale and Bennett, who remain almost the only first-hand authorities we have on the sperm whale. They were not in command, and were consequently at a great disadvantage for making observations; for the whole crew of a whaleship are co-partners in the venture, and the essential business of oil-getting must on no account be hindered, or there is trouble all around. And since their day, unfortunately, British shipowners have had little or no interest in the southern whale fishery, while none who know what a motley crowd constitute the crews of American whalers, will be surprised that no contributions to natural history come from that quarter. I am the more pleased, therefore, that in the course of my career as a seaman, it happened that I was induced some twenty-one years ago to join a whaleship in New Zealand for a long cruise in the Southern and Eastern seas. All the average sailors' usual ignorance of the differing characteristics of different whales was mine; but so interesting did I find the study of these great denizens of the deep sea, under my extended acquaintance with them, that I seized every chance I could obtain to learn whatever I could of them, without any idea at the time of putting the knowledge so gained to any practical use. The first occasion worthy of note here was also my initial encounter with a cachalot. We were cruising the wide stretch of ocean in the South Pacific known as the "Vasquez" grounds, and sighted a small pod of sperm whales, mostly sprightly young cows, under the guardianship of two or three immense bulls. We lowered four boats, and very soon the boat in which I happened to be "fastened" a medium-sized cow, who promptly returned the compliment by rising bodily beneath the boat and ripping the bottom out of it with her hump. Of course our connection with that whale was at once severed, the task of keeping our heads above water, with our boat hardly more than a bundle of loose planks beneath us, being amply sufficient to occupy all our energies until we were rescued. In the meantime the second mate had successfully harpooned and slaughtered another and much larger whale very near to us—so near, in fact, that we weltered in a gory sea lashed into foam by the monster's dying struggles.

Just before she died, we noticed her in the act of vomiting, and several masses of the matter ejected floated all around us. Some of them were exactly like large blocks of blanc-mange of no particular shape, almost white, but in some instances spotted with various colours. Many of the smaller pieces, however, were unmistakably portions of tentacles; lengths bitten or torn off. These it was most easy for me to identify, even under the awkward conditions, having been long familiar with the leaping or flying squid so often picked up on deck during heavy weather, or taken from the stomachs of albacore (*Scomber thynnus*), bonito (*Thynnus pelamys*), or dolphin (*Coryphæna hippuris*). This peculiar sight, although witnessed under such difficulties, made a very definite impression upon me, and as I had always examined the contents of the stomachs of such fish as I caught, so I longed to eviscerate the captured cachalot for a like purpose, although it was evident that she had probably ejected all the food that her maw had contained. Such anatomical pursuits are, however, quite out of the question at sea in a whaleship. Those who would essay the tremendous task of disembowelling a whale while it floats beside the ship, might indeed be rewarded by a find of ambergris worth more than the whole of the blubber and spermaceti, but the chances are not sufficiently inviting to tempt whalemen to undertake such herculean labours in addition to the already heavy toil of "cutting in."

Long afterwards, while cruising in Foveaux Straits, we caught a gigantic cachalot—the largest I think I have ever seen, even in that haunt of monstrous whales. We had an easy capture, for our prize had been previously attacked by some other ship, and in various parts of his body were the *disjecta membra* of seven exploded bomb-lances. Hardly was he fast alongside when one of those furious westerly gales so common on the southern shores of New Zealand sprang up, and it was well indeed for us that we had a good port under our lee. In spite of the load we had to tow, we arrived in Port William early the next morning with our prize all safe, and at once proceeded to cut him in. While engaged in this satisfactory, if filthy, operation, some Maories and half-breeds came off, and civilly asked if they might have the carcase when we had done with it. As it was of no earthly use to us, permission to take it when we cast it adrift was graciously accorded.

By dint of strenuous toil we got to the last joint of the vertebræ by 4 p.m., and, having disjointed it, the mountain of flesh floated majestically away, to be seized immediately by the waiting beach-men, who, with incredible labour, succeeded in landing the carcase near the western horn of the little bay.

That handful of men, six in all, laboured night and day for the best part of a week to get whatever oil was contained in the skeleton, bowels, and fat about the muscles. As we had finished our labour, a grand opportunity presented itself for examining the interior economy of this whale.

The vast cavity of the stomach contained a goodly assortment of cephalopoda in a more or less fragmentary condition; for I should have said that this whale, unlike most, had not ejected his food before his death. Judging from the sizes of the tails and the girth of some of the pieces, I estimated the largest of the squid at not more than six feet long, exclusive of the head. But what struck me as most peculiar was the large quantity of *bony* fish contained in the stomach of this cachalot. Blue and red rock-cod, groper, barracouta, and sea-bream were there—two or three bushels of them. Some were so recent as to be hardly soiled, and none bitten or damaged in any way except by digestive process.

How so vast and comparatively clumsy a creature could

succeed in obtaining such a large supply of active fish is incomprehensible to me, except upon the supposition that in waters like these, where fish abound in such incredible numbers, the cachalot cruises gently about with the great lower mandible hanging down (its normal position). The fish, mistaking the great livid cavernous throat for a cave of another kind, enter therein, to find egress impossible. But this is only a pious opinion of mine, unsupported by evidence other than the presence of fish where none could reasonably expect to find them, except under some such circumstances as I have supposed.

On another occasion we were cruising between Tongatabu (Friendly Islands) and Futuna, or Horn Island. Just before sunset a solitary sperm whale of goodly size was harpooned by us, and immediately sounded to a depth of 500 fathoms. He remained below the surface for about forty minutes, so that when he broke water again it was nearly dark. Of the terrors of that night I might say much, but this is not the place, neither do I think if it were that I could do anything like justice to the subject. Sufficient then to say that his agility and vitality were unequalled by that of any whale that I have met with, and it was well into the small hours of the morning before he gave up the contest. When day dawned we found that his lower jaw was twisted at right angles to his body, the result probably of some terrific conflict in the long ago. The outstanding portion of the jaw was almost covered with limpets of massive appearance, some measuring six inches across the base, and the intervening spaces were filled in with fringing barnacles of great length, giving him the semblance of a hoary beard. This alone was sufficient to endow a creature of such normal ugliness with an uncanny prehistoric sort of look—and there were not wanting members of our crew to exclaim that this was surely Davy Jones himself. But the chief peculiarity about this cachalot, and, indeed, the reason why I mention him here at all, was the extreme hardness and dryness of his blubber. Under ordinary conditions a whale of his size should have yielded at least seventy barrels of oil, but owing, I suppose, to the difficulty he must have had to procure food, it was only with an extraordinary expenditure of labour that we succeeded in extracting from him thirty-two barrels of oil. The opinion of all on board competent to give one was, that being unable to cope with the big squid, owing to the loss of his great weapon, the lower jaw, he had been driven to seek support on such food as he could obtain, and only managed to exist in a state of semi-starvation. Doubtless this accounted for his agility, and his fine drawn body, more like that of one of the Balænoptera than of a cachalot, went far to confirm the idea.

And now I come to the final instance for the present paper, but by no means the least important, at least to my mind, since it has settled several vexed questions for me finally. We were cruising in the Strait of Malacca, between the Nicobars and the Malay Peninsula, and had succeeded in killing a full-sized sperm whale. He had been a tough customer, needing all our energies to cope with him; but a well-directed bomb closed the negotiations just before sunset. As usual, he had ejected the contents of his stomach before dying, and we specially noticed the immense size of some of the masses floating about. By common consent they were about as large as our hatch-house, which measured 6 ft. × 6 ft. × 8 ft. I must very distinctly state that these masses were not square, but irregularly-shaped masses, bitten or torn off in blocks from the body of some gigantic squid.

The whale was secured alongside, and all hands sent below for a good rest prior to commencing to "cut in" at daybreak. I had the watch from eight bells to midnight, and at about 11 p.m. was leaning over the lee rail, idly gazing seawards, where the rising moon was making a broad lane of silvery light upon the smooth, dark waters. Presently there was a commotion in the sea, right in the way of the moon, and I immediately went for the night glasses to ascertain if possible the nature of it. In that neighbourhood there are several active volcanoes, and at first I judged the present disturbance to be one of these, sending up débris from the sea bed. A very short examination satisfied me that the trouble, whatever it might be, was not of volcanic or seismic origin. I called the captain, as in duty bound, but he was indisposed to turn out for anything short of actual danger, so the watch and I had the sight to ourselves. We edged away a little under the light draught of wind, so as to draw nearer to the scene, and presently were able to realise its full significance. A very large sperm whale was engaged in deadly conflict with a monstrous squid, whose far-reaching tentacles enveloped the whale's whole body.

The livid whiteness of those writhing arms, which enlaced the cachalot like a nest of mighty serpents, stood out in bold relief against the black boulder-like head of the aggressor. Presently the whale raised itself half out of water, and we plainly saw the awful-looking head of the gigantic mollusc. At our distance, something under a mile, it appeared about the size of one of our largest oil casks, which held 336 gallons. Like the rest of the calmar visible, it was of a peculiar dead-white, and in it gleamed two eyes of inky-blackness, about a foot in diameter. To describe the wonderful contortions of those two monsters, locked in a deadly embrace, is far beyond my powers, but it was a never-to-be-forgotten sight. The utter absence of all sound, for we were not near enough to hear the turmoil of the troubled sea, was not the least remarkable feature of this titanic encounter. All around the combatants, too, were either smaller whales or immense sharks, who were evidently assisting in the destruction of the great squid, and getting a full share of the feast. As we looked spell-bound we saw the writhings gradually cease, and the encircling tentacles gradually slip off the whale's body, which seemed to float unusually high. At last all was over, and the whole commotion had completely subsided, leaving no trace behind but an intensely strong odour as of a rocky coast at low tide in the full blaze of the sun. Since that night I have never had a doubt either as to the origin of all sea-serpent stories or the authenticity of the old Norse legends of the Kraken; for who could blame a seaman witnessing such a sight, and all unaccustomed to the close observation of whales, for reporting some fearsome monster with horrent mane and floating "many a rood." An interesting account of the French gunboat *Alecto* falling in with a calmar forty feet in length, lying on the surface in the North Atlantic, once fell into my hands. It told how those on board succeeded in getting a hawser passed round the creature, but in heaving it tight the rope cut its way through the soft gelatinous body, which floated away in halves, and gradually sank. I much regret now that I do not remember anything of the name or date of the publication in which this account appeared. In previous communications of my own to the press on the subject of sperm whales and their capture, I have incidentally alluded to these immense molluscs—*vide Land and Water*, September 29, 1894; *Chambers's*, March 24, 1894; *Pall Mall Gazette*, September 7, 1895; *Sheffield Weekly Telegraph*, November 2, 1895; *Good Words*, September 1895—a few of the most recent ones.

In closing these brief notes, owing to exigencies of space, I would like to add that the only place for accurate observations of these animals is at a bay-whaling station, such as the Prince of Monaco visited at Terceira. If he, with the appliances at his command, adheres to his resolve to pursue this great study, we shall soon be in possession of some splendid data. And he, or others on a similar errand, would find the best opportunities in the southern hemisphere, where the number of sperm whales are simply amazing around certain easily accessible spots.

FRANK T. BULLEN.

THE TORNADO.

THE exceptionally disastrous and destructive tornado which occurred at St. Louis, in the State of Missouri, shortly after five in the afternoon of May 27, draws more than ordinary attention to this class of disturbance, and excites, for a time at least, an interest in such phenomena. These disturbances are by no means of uncommon occurrence in the United States, but it is happily not often that a densely populated city falls directly in the track of the full fury of the storm.

Such well-known authorities as Ferrel, Finley, and Hazen have devoted much attention to tornadoes, and it is chiefly to the writings of these that we look for information. Several years ago the United States Signal Service published a report of the character of 600 tornadoes, and this clearly shows that no season of the year is exempt from their occurrence, but their greatest frequency is in the spring and summer, whilst in winter they are seldom experienced. Their occurrence is more common in April, May, June and July, than in any other months of the year. They almost always occur after the hottest part of the day, the hour of greatest frequency being between three and four in the afternoon, and they seldom begin after six in the evening. The centre of the disturbance is almost always formed in the southern or south-eastern segment of an ordinary area of low pressure, and a study of the weather charts, embracing a large area of the United States, shows that they are often several hundred miles from the centre of the parent disturbance. Those familiar with the formation and behaviour of our thunderstorm disturbances in England, will recognise an analogy to the tornado in their origin and motion with respect to the primary disturbance, of which they are mere secondaries. According to Finley, of the 600 tornadoes upon which he reported, the rotary movement of the whirling cloud was invariably from right to left, or the opposite movement of the hands of a watch. Ferrel remarks that this indicates either that the earth's rotation on its axis, as in cyclones, must determine the direction, or that the atmosphere has numerous whirls in this direction. The progressive motion of a tornado is almost always in a north-easterly direction, and here again there is a resemblance to the ordinary track followed by low-pressure areas in middle latitudes. The velocity of progression of the tornado cloud is said to vary from 7 to 100 miles an hour, the average rate being 44 miles. According to Finley the vortex wind velocities of the tornado cloud vary from 100 to 500 miles an hour, as deduced from actual measurements, and velocities of 800 to 1000 miles an hour have been reported. A wind velocity of 500 miles an hour is equal to about 750 lb. on every square foot. The width of the path of destruction, supposed to measure the distance of sensible winds on the sides of the storm's centre, varies from 40 to 10,000 feet, the average being 1085 feet, as deduced by Finley from a discussion of a large number of instances. The length of the tornado's track varies from 300 yards to about 200 miles, the average being 25 miles. The tornado has many features in common with the cyclone, but as experienced in the United States it is essentially different in many points, and in the interests of science it should be kept distinct. The tornado cloud assumes the form of a funnel, the small end drawing near or resting upon the earth, whilst the cloud and the air below it revolve about a central axis with inconceivable rapidity. Tornadoes differ from cyclones mostly in their extent, but both have vertical and gyratory circulations. A cyclone may extend over a circular area of one or two thousand miles in diameter, while a tornado rarely affects sensibly at any one time so great an area as a mile in diameter. In a cyclone the base is so great in comparison with the height, that the whole mass of gyrating air may be regarded as a thin disc, and consequently a large amount of the force is spent in overcoming the frictional resistances at the earth's surface. In a tornado the height is so great in comparison with the base that the gyratory velocity is almost wholly free from friction. The late Prof. Ferrel, who ranks probably higher than any other authority on winds and storms, was of opinion that a cyclone "requires, in addition to the state of unstable equilibrium for saturated air, such a disturbance in the general equality of temperature over a considerable area that there is a central and somewhat circular area of higher or lower temperature, from which arises a vertical, and consequently a gyratory, circulation"; while the tornado "simply depends upon conditions which give rise to very local disturbances merely." Without doubt the conditions which characterise the tornado are also common to such phenomena as waterspouts, cloudbursts, whirlwinds, wind-blasts, and others of a like nature

An excellent descriptive report of the St. Louis catastrophe appeared in the *Daily Telegraph*, and is abridged below. The report shows that the tornado had many features common to such disturbances. The occurrence of "three separate and distinct storms," which subsequently became one, is especially alluded to by Ferrel in his general description of tornadoes. He says: "As the tornado originates in air in the unstable state, it often happens that there is about an equal tendency in the air of the lower stratum to burst up through those above at several places in the same vicinity at the same time. Each of these gives rise to a separate and independent gyration in the atmosphere, and a small funnel where they are of sufficient violence · but generally, as they increase in dimensions and violence they interfere with one another and finally become unite into one." The reported wind velocity of eighty miles an hour appears to be an estimate formed outside of the central area of the storm. In England the wind has attained a velocity of 107 miles for a whole hour, registered at Fleetwood in the gale of December 22, 1894, and at Holyhead on February 20, 1877, the anemometer registered an hourly rate of 200 miles for a short time in the gusts.

The weather at St. Louis nearly the whole of Wednesday, May 27, was unusually warm and oppressive. There was not a breath of wind, and the people suffered greatly from the heat. About four o'clock in the afternoon the western horizon became banked with clouds piled one on top of the other, with curling edges tinged with yellow. The sight was beautiful, but somewhat terrifying. Then a light wind sprang up, followed by sudden and ominous darkness.

The gloom deepened, and when the storm actually burst upon the city pitch darkness prevailed. These strange atmospheric disturbances had created anxiety among the people abroad in the streets, but not alarm.

There seemed to be three separate and distinct storms. They came from the north-west, from the west, and from the south-west, but when these reached the river they had become one.

Before the great mass of menacing clouds which were hanging over the villages of Clayton, Fernridge, Eden, and Central gave forth their contents funnel-shaped formations shot out of them. Some of these funnels seemed to be projected into the air; others leaped to the earth, twisting and turning like some wounded monsters. Lightning played about them. There was, in fact, a marvellous electrical display. Then came the stupendous outburst.

From the great black clouds came a strange, weird, crackling sound, at times stronger than the incessant peals of thunder, which had from the first been a terrifying feature of the storm. The funnels enveloped the western side of the city, and within thirty minutes of their first appearance on the horizon they were dealing out destruction.

So irresistible was the storm in its power, and so much greater in its magnitude than any other previously recorded in America, that some of the staunchest business blocks in St. Louis, considered absolutely tornado-proof, went down before it as though they were mere barns. Iron girders were torn from their massive fastenings and carried blocks distant. Roofs that were braced

and held by every device known to architects and engineers were wrenched off and hurled into the streets. The destruction of telegraph material was phenomenal. The poles were blown down in long rows, not singly, but in groups of a dozen or more at a time.

The western end of the Eads Bridge—admittedly one of the finest in the world—was destroyed. The same fate overtook other splendid bridges spanning the Mississippi.

The scene on the river at the moment the cyclone passed over it was awe-inspiring. The river tossed and boiled as though it was a whirlpool. Great waves struck the vessels and swamped them. Some steamers were blown bodily high up upon the banks, and others were twisted right round. Others, again, after being torn from their moorings disappeared in the torrent and were never more seen. As a rule the smaller craft did not live in the terrible sea for a minute, but just capsized and sank.

In the smaller places through which the tornado passed the terrible funnels rose and fell as they swiftly moved, and thus the line of destruction was not continuous. But whatever stood in their path was either destroyed or badly damaged, and all this destruction was done within the space of one hour.

About five hundred persons are reported to have been killed during the passage of the tornado, and more than seven hundred injured. The path followed is now shown to be a well-defined track about half a mile wide and four miles long.

NOTES.

THE second of the two annual conversaziones of the Royal Society, to which ladies as well as gentlemen are invited, will take place on Wednesday, June 10.

THE University of Paris will be represented at the forthcoming jubilee of Lord Kelvin, by MM. Moissan, Lippmann and Picard. The Royal Astronomical Society has appointed the President, Dr. A. A. Common, F.R.S., as its representative upon that occasion; and the Senate of the University of Sydney have appointed the Chancellor, Sir William Windeyer, and Prof. Liversidge, F.R.S., the Dean of the Faculty of Science, to represent them.

WE have referred from time to time to the approaching eclipse of the sun. During the last week some members of the expedition to Japan have sailed. From information received from the Japanese Minister, the reports of the bad weather chances at the station chosen are more than confirmed. The mean of the last five years gives for August—

	Days
Clear ...	0
Cloudy	22
Rain or snow	22

With regard to the Norwegian parties, Dr. Common will occupy a station at Vadsö, and in his neighbourhood will be Dr. Copeland. Mr. Norman Lockyer intends, if possible, to observe on the south side of Varanger fjord, if a suitable anchorage and observing station can be found sufficiently near the totality line. This point will be inquired into by Captain King Hall, of H.M.S. *Volage*, which will be detached from the Training Squadron for this purpose.

LIEUTENANT PEARY is making arrangements for another trip to Greenland, one of the objects being to bring back for the Philadelphia Academy of Sciences the forty-ton meteorite discovered by him last year, being the largest in the world. He will shortly give an account of his important explorations in Northern Greenland to the Royal Geographical Society.

THE Council of the British Medical Association desire to remind members of the profession engaged in researches for the advancement of medicine and the allied sciences, that they are prepared to receive applications for grants in aid of such research. Applications for sums to be granted at the next annual meeting must be made on or before June 15, in writing, addressed to the General Secretary, at the office of the Association, 429 Strand, W.C.

THE Commissioners of the proposed zoological park of New York City have selected as the site that portion of Bronx Park lying south of Pelham Avenue, comprising two hundred and sixty-one acres. It is expected that their selection will be approved. The site is near the new botanical garden, and New York City will thus acquire in this year ample zoological and botanical gardens and an aquarium.

PROF. N. L. BRITTON has been appointed superintendent of the new botanical garden of New York City.

THE death is announced of M. Raulin, Professor of Industrial and Agricultural Chemistry in the University of Lyons.

THE Paris correspondent of the *Times* announces the death, at the age of eighty-two, of M. Daubrée, the eminent geologist. Born at Metz, and educated at the Polytechnic School, Paris, he was sent on a geological mission to Algeria, and from 1839 to 1855 was a Professor at Strasburg University. He was then promoted to a chair at the School of Mines and the Natural History Museum, Paris. His experimental researches, on the action of rapidly moving and high-pressure gases on rock masses, and the application of the results to peculiar rock formations, are still fresh in the minds of every one interested in geological problems.

WE regret to notice the death of Sir J. Russell Reynolds, F.R.S., on Friday last, at the age of sixty-eight. He was educated at University College, London, where he became Professor of the Principles and Practice of Medicine in 1865. Four years later he was elected a Fellow of the Royal Society. He was President of the British Medical Association in 1895, in which year he also received the honorary LL.D. degree at Aberdeen, and recently a similar honour was conferred upon him by the Edinburgh University. On the death of Sir Andrew Clark, in 1893, he was elected President of the Royal College of Physicians, which post feeble health compelled him reluctantly to relinquish at the recent annual election. Sir Russell Reynolds' works on diseases of the brain and spinal cord are valuable contributions to medical literature, and the "System of Medicine," of which he was the editor, stands as a proof of his sound sense and good judgment.

THE forty-first annual exhibition of the Royal Photographic Society will be held from September 28 to November 12, in the gallery of the Royal Society of Painters in Water Colours. Negatives, transparencies, photo-mechanical prints, stereoscopic work, photographs of purely scientific interest, photographs coloured by scientific or mechanical means, and photographic apparatus will be admitted. Foreign exhibitors are invited to contribute photographs or apparatus. Exhibits must be received by the Secretary of the Royal Photographic Society, on or before September 9.

THE President of the Board of Trade has appointed a Committee, consisting of the following gentlemen, viz.:—Lord Blythswood (chairman), Sir Benjamin Baker, K.C.M.G., F.R.S., Sir J. Lowthian Bell, Bart., F.R.S., Prof. Wyndham Dunstan, F.R.S., Prof. A. B. W. Kennedy, F.R.S., Major F. A. Marindin, R.E., C.M.G., Mr. E. P. Martin, Prof. W. C. Roberts-Austen, C.B., F.R.S., Dr. T. E. Thorpe, F.R.S., Prof. W. C. Unwin, F.R.S., and Mr. E. Windsor Richards—to inquire as to the extent of loss of strength in steel rails produced by their prolonged user on railways under varying conditions, and what steps can be taken to prevent the risk of accidents arising through such loss of strength. Mr. W. F. Marwood, of the Board of Trade, has been appointed to act as Secretary to the Committee.

By the will of the late George Yeoman Heath, Professor of Surgery in the University of Durham, and President of the Durham College of Medicine, a sum of £200 is awarded every second year for a surgical essay. We learn from the *Lancet* that the second award will be given to the writer of the best essay on "Congenital Deformities, their Pathology and Treatment." All graduates in medicine or in surgery of the University of Durham are eligible to compete for this scholarship, and the essay, which must be type-written or printed, should be delivered to the trustees not later than March 31, 1898. The essay, together with any specimens, drawings, casts, microscopical preparations, or other means of illustration accompanying it, will become the property of the College, though by permission the essay may be printed for general circulation by the Heath scholar. This is one of the most valuable surgical prizes in the kingdom, and the competition should be keen.

THE Société helvétique des sciences naturelles will hold its seventy-ninth meeting from August 2 to 5, at Zürich. This will be the sixth occasion on which the Society has met at that place, and it will do so very appropriately in August next, because the Zürich Societé des sciences naturelles—the oldest of those existing in Switzerland—celebrates this year the 150th anniversary of its foundation. A number of papers have already been promised in the various sections into which the congress will be divided. All who desire to be present, or to contribute papers, are requested to communicate with the Secretary, Dr. Aug. Aeppli, Kinkelstrasse, Zürich IV., before July 15. The Swiss Societies of geology, botany, and entomology will meet at the same time as the Société helvétique des naturelles sciences. A geological excursion has been organised, under the direction of Prof. A. Heim, and there will also be a botanical excursion. Every one interested in the advancement and unity of science is cordially invited to attend the meeting.

AT the Electrical Exposition in New York, a few days ago, messages were sent all round the world, and received back in a few minutes. A vast audience hailed with enthusiasm the return of the messages from their long circuits. The first surprise was the announcement that a message had been received within four minutes after sending it, having meanwhile twice crossed the continent of America and the Atlantic Ocean. At London the message was rewritten, and sent on to Tōkiō, and back to New York by a circuitous route, covering 27,500 miles in about fifty minutes. Another message, making another circuit of equal length, returned a few minutes later; while a message sent all round South America, came back in twenty-three minutes. The messages were dictated by Chauncey M. Depew, President of the New York Central and Hudson River Railroad, and Mr. Adams, President of the Niagara Falls Power Company. Mr. Edison received one or two of them. The messages will be preserved in the Smithsonian Institution, together with copies of all papers throughout the world that published them, so far as they can be obtained.

A SLIGHT shock of earthquake is reported to have been felt in West Cornwall, at five minutes to seven on Friday morning, May 29. An earthquake shock also occurred in Dumfriesshire, and a noise resembling a distant peal of thunder was heard. Furniture and crockery were agitated by the movement, which lasted a few seconds, and does not appear to have been attended by any damage of consequence.

IT appears from the annual reports of the six Pasteur Institutes existing in Russia and Poland (St. Petersburg, Moscow, Warsaw, Odessa, Kharkoff, Samara, and Tiflis), that during the year 1892 no less than 2886 persons applied at the Institutes for anti-rabic treatment, as against 2976 in 1891. Out of them, 2763 persons were put under treatment. The percentage of deaths was, as usual, very high for wolves' bites, viz. from 2·22 to 37·5 per cent. in the different institutes; while for dogs' bites the percentage of deaths was insignificant, that is, from 0·5 to 1·05.

AMONG many articles of interest in the May number of the *Essex Naturalist*, is one by Mr. Henry Laver on "Potash Making in Essex: a lost rural industry." In the beginning of this century the preparation of alkali by the lixiviation, in large iron or copper pots, of the ashes of wood, straw, grasses, and other vegetable refuse, was a very common rural industry in Essex, the "pot-ash" thus produced being frequently converted at once into soap. The decay of this industry must be chiefly attributed to the production on the large scale of the cheaper soda-ash from salt, and to the introduction of coal instead of wood as fuel. Mr. Laver contrasts the healthful conditions under which the potash was produced a century ago, with those under which soda is produced at the present day; a contrast much to the disadvantage of the latter.

IN the *Comptes rendus* for May 4, one of Maxwell's early proofs of the "error law" of distribution of velocity in the kinetic theory of gases receives severe criticism in the hands of M. J. Bertrand. In the work referred to, Maxwell claimed to have solved the problem of finding the law of distribution of speed in a system of molecules without making any assumptions as to the nature of these molecules or the forces between them beyond that, on account of the absence of all regular order, everything was distributed equally in all directions. After comparing Maxwell's problem to the favourite schoolboy question, "Given the dimensions of a ship, find the age of its captain?" M. Bertrand points out that the proof in question really involves a very important assumption, and one which he appears to regard as unjustifiable. If x, y, z be the velocity-components of a molecule in three directions at right angles, Maxwell states, or rather *assumes*, that the velocity x has no influence on the velocities y and z, their directions being independent, and hence that the number of molecules whose velocity-components lie between the limits $dx\,dy\,dz$ is represented by an expression of the form

$$N\,\phi(x)\,\phi(y)\,\phi(z)\,dx\,dy\,dz.$$

M. Bertrand considers that the x component *does* influence y and z, and that by neglecting this influence, which is great, Maxwell obtained a solution of an insoluble problem.

THE kinetic theory also forms the subject of an article by Prof. Boltzmann in *Wiedemann's Annalen*, in which he attacks some views recently enunciated by Herr Zermelo. Prof. Boltzmann regards the Boltzmann-Maxwell Law as a theorem in probability, rather than a principle of abstract dynamics. There is nothing to preclude the *possibility* of the molecules of a gas behaving at any instant in a totally different manner from that indicated by the law, but the greater the number of molecules the more improbable does such a departure from the law become.

IN the *Botanical Gazette* for April, an interesting case of mimicry is described, the seeds of the "Philippine island bean" from the coast near Manila, so closely resembling the quartz pebbles among which they fall, in shape, size, colour, lustre, hardness, and stratification, as to be indistinguishable from them except by a very close examination. The size and shape of the beans are both very variable, ranging from 10 to 23 mm.; some perfectly resemble well-rounded beach pebbles, while others mimic pebbles which have been broken across. Their colour varies from moderately dark to light drab, some giving a faint greenish tinge; others resemble pebbles of chalcedony or of crystallised quartz. Nearly all the specimens show a series of approximately parallel darker lines passing round, very suggestive of stratification. All are quite hard, cut only with difficulty

with a knife, and give a clinking sound when shaken together in the hand. They are not affected by soaking in sea-water.

A MONOGRAPH of the *Crambidæ* (or grass moths) of North America, by Dr. C. H. Fernald, was issued by the Massachusetts Agricultural College in January of the present year. Much care seems to have been bestowed upon this essay, which extends to ninety-three pages, and is illustrated by three plates of details, and five coloured plates of quite unusual excellence, as well as occasional woodcuts.

THE interesting address on Meteorological Observatories, delivered by Mr. Richard Inwards before the Royal Meteorological Society, early in this year, is published in the April *Journal* of the Society, with illustrations of the Temple of the Winds, Athens, Greenwich Observatory, and Kew Observatory. Mr. Inwards has brought together a large amount of general information on meteorological observatories in various parts of the world.

THE report of the Marlborough College Natural History Society for 1895 has just been issued, and contains numerous articles, not only on local ornithology, entomology, botany and meteorology, but also on archæology, astronomy and chemistry. There are also illustrations of Wayland Smith's Cave, and of High Street, Marlborough, after the great storm of June 26, 1895. Times seem to have changed since classics and mathematics were regarded as the only subjects worth thinking about at a public school.

BY order of the Government of Madras, that Observatory has published a valuable series of daily, monthly, and yearly meteorological means, as a supplement to the volumes already issued giving the meteorological observations from 1796 to 1890. They are not intended as a discussion of those observations, but have been prepared specially for use in various offices which issue daily weather charts of Indian regions. The rainfall values extend over eighty years, and the barometrical means over fifty years.

WE have received the nineteenth report of the State Entomologist on the noxious and beneficial insects of the State of Illinois. It is the eighth report of S. A. Forbes, for the years 1893 and 1894 (1896); with a separately issued appendix on the Mediterranean Flour Moth (*Ephestia kuehniella*, Zell.) in Europe and America, by W. G. Johnson, Assistant Entomologist. These reports are drawn up in the usual elaborate American manner, and the main report is chiefly devoted to the Chinch Bug (*Blissus leucopterus*, Say) and to White Ants, and is illustrated with thirteen plates of a very miscellaneous character in connection with the ravages of these and other insects. Much attention is given in this report to experiments on the dissemination of vegetable parasites among insects.

THE latest number of the *Journal* of the Asiatic Society of Bengal (vol. lxiv. part ii. No. 3), contains articles of unusual interest and variety. Nearly three-quarters of the part are taken up with a list of the Butterflies of Sumatra, by Mr. De Nicéville and Dr. Martin; while Messrs. King, Prain and Pantling write on *Papaveraceæ*, new orchids from Sikkim, and on a new species of *Renanthera*. But in addition to these more technical entomological and botanical papers, Surgeon Lieut.-Colonel Ranking writes on artificial immunity to snake venom by inoculation or internal application, in ancient and modern times (compare Prof. Fraser's articles in recent numbers of NATURE); and Mr. Frank Finn commences a series of contributions to the theory of warning colours and mimicry, by recording his experiments in feeding a Babbler (*Crateropus canorus*) on protectively-coloured butterflies and other insects.

WE note the appearance of three new volumes in the extensive series which constitutes the Encyclopédie Scientifique des Aide-Mémoire, published by MM. Gauthier-Villars and G. Masson. One is the third volume on "Géométrie Descriptive," and it deals with changes of planes of projection, rotations, trihedrons, and polyhedrons. In "Calcul de Temps de Pose en Photographie," by M. H. Boursault, the complex problem of the conditions which affect calculations of the time of exposure is treated in a very satisfactory manner. Scientific photographers will find much exact and serviceable information in M. Boursault's little volume. A volume on "Les Tramways," by M. R. Seguela, is an account of methods and materials employed in the construction of tram-lines in France. the United States, Great Britain, and other countries.

THE volumes in Stanford's Compendium of Geography and Travel, now in course of reissue, have been subjected to such thorough revision and considerably enlargement, that they are practically new books. The work on Asia, for instance, first published in 1882 in one volume of 750 pages, has been expanded into two volumes of about 550 pages each, and the first, dealing with northern and eastern Asia, has just been published by Mr. Stanford. Mr. A. H. Keane is responsible for this volume, and he may be complimented upon the thoroughness with which he has performed his task of revision. If the forthcoming volume on southern and western Asia is as satisfactorily done as the one now published, the whole will form an admirable account of the geography of the Asiatic continent, and one which accurately records the results of the important expeditions made during the past few years.

RECENT events in the Transvaal have had the effect of increasing the number of visitors to the South African Museum, according to the annual report of the Trustees; and this connection is borne out by the fact that during January of the present year the number of visitors was 5574, three-fourths of which consisted of country people, while the other fourth consisted chiefly of new arrivals and inhabitants of the Cape Peninsula. Visits from the inhabitants of Cape Town are said to be comparatively rare. Several attempts were made during last year to procure some of the large South African mammals, but the Trustees have not yet been successful in obtaining specimens of the elephant, giraffe, hippopotamous, &c., to replace the defective ones in the Museum collection. A number of fossil remains procured by Mr. E. H. L. Schwarz from the Prince Albert district of the colony are being developed by him. Fragments of one of the fossil reptiles have been sent to Prof. Seeley for development and identification, and the animal has been provisionally named by him *Tetracynodon*. Reference is made in the report to the resignation of the Curator, Mr. R. Trimen, and the appointment of Mr. W. L. Sclater as his successor. We notice that on account of the increased requirements of the new Museum, the buildings of which were taken over by the Trustees at the end of last year, the annual subsidy has been raised from £1600 to £2000.

WE have received the meteorological results of the observations taken at the Bangalore, Mysore, Hassan and Chitaldroog observatories for the years 1893 and 1894. The stations were established by the Mysore Government, in accordance with the desire of the Government of India. In addition to the usual tables, the work contains diagrams giving the mean daily and monthly values of the various elements, and a map of the Mysore Province, showing the average annual rainfall for the twenty-five years (1870–1894). These diagrams exhibit at a glance the nature of the weather changes, much more easily than could be gathered from a mere collection of figures. They show clearly that the rise of temperature from the cold of January to the heat of March and April is much more rapid in Mysore than

at Madras, where the climate is tempered by the influence of the sea. It is interesting to observe the interval between the mean dry and wet-bulb temperature throughout the year, and the daily range of temperature; the latter varies greatly, amounting to nearly 34° at Hassan, in January. The highest shade temperature in the two years was 99°·5 at Chitaldroog, in April 1893.

THE *Quarterly Journal* of the Geological Society for May is an unusually thick number, and its contents cover almost as wide a range of geological subjects as could be brought together. Palæontology is represented by the presidential address on the history of the Crustacea by Dr. Woodward, who also contributes papers on Cretaceous Crustacea from Vancouver, and on the only known fossil Octopod; while Mr. C. W. Andrews discusses the Plesiosaurian skull, and Mr. P. Lake continues his work on a group somewhat neglected of late years by British geologists—the Trilobites—with a study of the Silurian species of *Acidaspis*. In stratigraphy, Dr. Hicks contributes a paper in which he claims the Morte Slates as Silurian, and reopens in a new manner the North Devon controversy, while Miss Elles and Miss Wood show that there are Llandovery beds in the Conway district. The British Cretaceous rocks are subjected to a most detailed correlation—as regards the Speeton series by Mr. Lamplugh, and as regards the Cenomanian by Messrs. Jukes-Browne and Hill; the former author urging that some of the strata dealt with are strictly Jurassic, while the two latter show that the true Cenomanian of France represents our Lower Chalk only, and not our Upper Greensand. The only Tertiary geology in the journal concerns the Basaltic plateaus of North-western Europe and the river-system of the old land across which the lavas were poured, described in a most interesting paper by Sir Archibald Geikie. This last paper, along with one on a part of the same subject—the Skye granophyres—by Mr. Harker, represents also the petrological contributions to the journal. Important evidence is adduced by Prof. Edgeworth David of a Permo-Carboniferous glaciation of Australia. Finally, Prof. Hull's paper on the geology of the Nile, and Mr. Hill's, on transported Boulder Clay, must not be forgotten.

AN elaborate monograph on "The American Lobster," by Prof. F. H. Herrick, forming a part of the *Bulletin* of the United States Fish Commission for 1895 (pp. 1–252), has been issued as a separate publication. The memoir contains the results of a masterly study of the habits and development or general biology of the lobster, and is illustrated with the lavishness which is a feature of official publications of the United States. Until comparatively recent years the lobster was singularly neglected by naturalists; nevertheless, Prof. Herrick gives at the end of his memoir a list of more than two hundred papers referring to the Crustacea, of which the lobster may be styled the king. The subjects of the chapters in the present contribution to this literature are: habits and environment, reproduction, moulting and growth, defensive mutilation and regeneration of lost parts, large lobsters, enemies of the lobster, the tegumental glands and their relation to sense organs, variation in colour and structure, structure and development of the reproductive organs, habits of the lobster from time of hatching until the period of maturity, history of the larval and early adolescent periods, and embryology of the lobster. It will be seen from this brief statement that Prof. Herrick has studied many phases of the general biology of the lobster, and in all of them he adds to the previous knowledge of the subject. His observations are of scientific value, and many of the facts described, more particularly those relating to the larval development and reproduction, have important economic bearings. After some statistics pointing to the decline of the lobster fishery in the United States, Prof Herrick remarks: "Civilised man is sweeping off the face of the earth, one after another, some of its most interesting and valuable animals by a lack of foresight and selfish zeal unworthy of the savage. . . . Thus, as we shall see, the American lobster occupies only a narrow strip along a part of the North Atlantic coast, and while it is probably not possible to exterminate such an animal, it is possible to so reduce its numbers that its fishing becomes unprofitable, as has already been done in many places. The only ways open to secure an increase in the lobster are to protect the spawn-lobsters, or to protect the immature until they are able to reproduce, or to take the eggs from the lobsters themselves, and hatch them artificially." For the sake of the persons engaged in the lobster fishery, it is to be hoped that measures will be taken in time to prevent its further decline in the United States.

THE additions to the Zoological Society's Gardens during the past week include a Caracal (*Felis caracal*) from India, presented by Captain E. F. Carter; a Spotted Cavy (*Cœlogenys paca*) from Trinidad, presented by Dr. F. G. C. Damian; a Common Otter (*Lutra vulgaris*), British, presented by Mr. Henry Laver; a Blue and Yellow Macaw (*Ara ararauna*) from South America, presented by Mrs. Browning; a —— Deer (*Cariacus paludosus*, ♂) from Paraguay, two Green-winged Doves (*Chalcophaps indica*), two White-backed Pigeons (*Columba leuconota*) from India, four Alligators (*Alligator mississippiensis*) from the Mississippi, four Dandin's Tortoises (*Testudo dandinii*) from the Aldabra Island, deposited; two Thick-tailed Opossums (*Didelphys crassicaudata*) from South America, four Gouldian Grass Finches (*Poëphila gouldiæ*), two Crimson Finches (*Estrelda phaëton*) from Australia, purchased; a Sœmmerring's Gazelle (*Gazella sœmmerringi*, ♂), two Striped Hyænas (*Hyæna striata*), an Egyptian Ichneumon (*Herpestes ichneumon*), two Libyan Zorillas (*Ictonyx lybica*), two Fennec Foxes (*Canis cerdo*), two Ruppell's Vultures (*Gyps rüeppelli*), four Egyptian Vultures (*Neophron perenopterus*) from Egypt, received in exchange.

OUR ASTRONOMICAL COLUMN.

THE RING NEBULA IN LYRA.—The appearance of the brightest of the ring nebulæ, as seen with the Lick 36-inch refractor, is described by Prof. Barnard in *Ast. Nach.* No. 3354. The aperture of the ring was filled with a feebler nebulosity, which was estimated to be nearly midway in brightness between the brightness of the ring and the darkness of the adjacent sky. This aperture was more nearly circular than the outer boundary of the nebula, so that the ends of the ring were thicker than the sides. The following end of the ring had a slightly greater extension, which was less bright than the ring itself, and the entire nebula was of a milky colour. The central star was usually seen, but was never a very conspicuous object. The brightest region of the nebula lies in the northern part. Micrometric measurements of the nebula gave the following mean results:—

Position angle of major axis ...	65°·4
Outer major diameter	80″·9
Inner major axis	36″·5
Outer minor axis	58″·8
Inner minor axis	29″·4

A magnifying power of 520 was generally employed.

VARIABLE STAR CLUSTERS.—The discovery of a large number of variable stars in certain star clusters was announced a few months ago by Prof. E. C. Pickering (NATURE, vol. liii. p. 91). Since then a special investigation has been made of the variables forming part of the cluster M. 5 Serpentis, N.G.C. 5904 (*Ast. Nach.* 3354). Forty-five photographs of this cluster have been measured by Miss Leland, and the measures include the greater portion of the forty-six variables previously discovered. The periods of these variables are in general very short, not exceeding a few hours. One of these, designated No. 18, which follows the centre of the cluster about 6′ and is south 5′, has a probable period of 11h. 7m. 52s., or 0·4638

days. The coordinates of the light curve of this variable are as follows:—

Days.	Mag.	Days.	Mag.
0·00	13·50	0·25	14·73
0·05	13·87	0·30	14·73
0·10	14·35	0·35	14·72
0·15	14·70	0·40	14·65
0·20	14·72	0·45	13·56

It thus appears that the star remains about minimum brightness during half the period, while the maximum luminosity is of relatively short duration; the decrease in light is rapid, and the rate of increase still more rapid. The succession of changes does not seem to correspond with those of any previously known class of variable stars.

RECENT RESEARCHES ON RÖNTGEN RAYS.

THE novelty of Prof. Röntgen's skeletal photographs has almost worn off, and the field of research opened up by his observations is now mainly occupied by scientific workers, who are endeavouring to analyse the rays, and to extend the knowledge of their characteristics, rather than to produce startling pictures capable of exciting the wonder of the general public. But though the interest of scientific dilettantes has waned, the investigators who remain in the field are still so numerous that it is hardly possible to keep in touch with the multitude of observations published; and published in some cases, perhaps, a little prematurely. A number of interesting results have been recorded from time to time among our "Notes"; but so many papers and communications have been received during the past few days, that they are now brought together for readier reference, as has been done in several previous issues of NATURE.

Attempt to Polarise Röntgen Rays.

Dr. John Macintyre, whose observations on the capabilities of Röntgen rays have formed the subject of several letters and notes in these columns, has sent us an account of an attempt to polarise the rays. Different views have been expressed about the possibility of polarising the rays by means of tourmalines, and although Dr. Macintyre's experiments seem to indicate a negative result, they are of such importance that they deserve to be put on record.

The source of electricity was the main, and the measurements across the terminals (with Lord Kelvin's cell-tester and ampere gauge) were 10 volts and 10 amperes. The spark of the Rhumkorff coil was 6 inches, and a mercury interrupter was used. An ordinary Crookes' focus tube, enclosed in cardboard to exclude all light, was excited by the above, and the vacuum carefully arranged to give the maximum fluorescence by gently heating the bulb with a spirit-lamp. Screens of barium platino-cyanide, potassium platino-cyanide, and lithium-rubidium-platino-cyanide were tried. The two tourmalines were got as nearly alike as possible, the measurements of each being: length, 47 mm.; breadth, 12 mm.; thickness, 2 mm.; and the experiments were carried out in a dark room.

In the first experiment, on placing one tourmaline between the source of the Röntgen rays and the screen, and directly in contact with the latter, a distinct shadow was seen due to absorption of the rays. On placing the second tourmaline parallel with the first, a difference in density of the shadow was immediately observed. When the tourmalines were gradually turned at right angles to each other, a dark square area could be seen where the two crossed. A source of error was, however, suggested in this experiment. One of the tourmalines could not be in as close contact with the screen as the other; and on account of the manner in which the Rontgen rays pass from a point on the platinum plate in such a Crookes' tube, differences were observed in the shadows of the four arms of the cross formed by the tourmalines. For example, (1) if the horizontal tourmaline were next to the screen, and the vertical one behind it, the two arms above and below the square dark central area were less sharply defined than the two arms on each side of it, and consequently the shadows appeared to be different. (2) Although on the square portion corresponding to where the tourmalines crossed, one got a darker shadow still, it might only be due to the difference in thickness of the two layers.

A second observation was then made. One of the tourmalines was broken in two portions, and one of these was placed parallel with and the other perpendicular to the other tourmaline. Again the dark square area was seen by direct vision. Dr. Macintyre could not say, however, that the density was greater than where the other portion of the broken tourmaline was laying parallel with the whole one. This rather suggested that the square dark area was caused by difference of density only. In a third series of observations photographs were taken with different exposures—one with a single flash of the tube, due to one interruption of the coil; others with much longer exposures, but in all the same difficulties in distinguishing between the two conditions arose. (Copies of these photographs have been received from Dr. Macintyre.) In the first photograph a shadow of one tourmaline was obtained, proving the absorption of some of the Röntgen rays. In the second photograph, of one whole tourmaline and a portion of the other, a greater density can be noted where two layers are lying parallel with each other than where only one tourmaline interferes with the rays. The third photograph shows the unbroken tourmaline covered at one part by a portion of the broken tourmaline lying parallel with its axis. The other part of the broken tourmaline is placed at right angles, and Dr. Macintyre raises the question whether the density of the square area is greater than where the two tourmalines are lying parallel with each other. In his opinion, the photographs bear out the observations by direct vision, and appear to give negative results; and an examination of the two photographs which form the result of his crucial experiment, leads us to conclude that there is not any appreciable difference of brightness between them.

Röntgen Rays and the Resistance of Selenium.

Mr. J. W. Giltay, Delft, Holland, has sent us the following important communication on the influence of Röntgen rays upon the resistance of selenium.

Some weeks ago, the possibility of Röntgen rays having an influence on the resistance of selenium occurred to me. I made a preliminary experiment to put this idea to the test, but, probably owing to the poor state of my induction coil, I failed to get any effect. Want of time prevented me from trying again with another coil.

I told my failure to Prof. H. Haga, of Groningen University, who kindly undertook to investigate the subject. The selenium cell I made for him was of the Shelford-Bidwell type (NATURE, November 18, 1880), the working surface was 20 × 44 mm. The resistance of this cell was in darkness 31,600 ohms, in diffuse daylight it was about 15,300.

Prof. Haga with this cell got the following results, which I publish in this letter with his full approval.

The Crookes' tube he used was of the ordinary pear form (not a focus tube), and highly evacuated, giving undoubtedly a very strong Röntgen effect. The induction coil was one of Ruhmkorff's, of a length of 60 cm.; the battery for driving the coil consisted of five accumulator cells.

The distance between the selenium cell and the under part of the tube was 3 cm. The cell was covered with pasteboard, and over this was laid a thick sheet of zinc. The resistance of the cell was now measured by the bridge method, one dry cell acting as the battery, contact being of course made only momentarily. The resistance in the dark was found to be 31,600, as I remarked before. Now the induction coil was started and worked during just one minute; the resistance of the cell was then immediately measured again, and found to be exactly the same. This proved the wires carrying the induced currents and the coil itself to have no influence on the cell.

Now the zinc plate was removed and replaced by two thin aluminium sheets (two instead of one, to prevent heat rays falling on the cell). The coil was now worked during one minute, and immediately after stopping it the resistance of the cell was taken. This was now found to be 26,400.

The resistance was not measured *during* the radiation, else it would probably have been found to be a little less than 26,400, but immediately after the coil having been stopped. The measuring of the resistance took about one minute. After having left the cell at rest during 20′, the resistance had risen to 29,500 again.

Prof. Haga made several experiments, always with the same qualitative results.

A simple kind of bolometer, consisting of strips of tinfoil (11·85 Ω) did not show any change of resistance by Röntgen radiation.

It follows from these experiments of Haga's, that Röntgen rays act on the resistance of selenium in the same way as light and heat rays do. I think selenium will be found to be very useful in investigating the opacity of different substances for the Röntgen rays, and also for experimental work on the polarisation of those rays, as the deflection of a galvanometer is much easier to appreciate than the value of the photochemical action of the rays. It also follows from these experiments, that selenium is a very unfit material for making photometers.

It must always be kept in mind, when working with selenium, that the cell takes very little time in diminishing its resistance under the action of light, or other rays, but that it takes a much longer time (often half an hour or so) to return to its state of high resistance. It follows from this, that if one wishes to compare the action of two emissions, one must begin with the feebler radiation and afterwards let the stronger radiation hit the cell.

The Nature of Röntgen Rays.

The nature of Röntgen rays is so far from being settled, that the following remarks by Prof. W. N. Hartley, in favour of the ultra-violet theory, will be read with interest :—

The great doubt which prevails as to the nature of Röntgen rays arises from the fact that it is difficult to imagine radiations which make their existence manifest in a manner which, at first sight, appears very extraordinary.

Their intractability to the action of ordinary refractive media, and the facility with which they are transmitted by matter which has the property of absorbing light, has led to their being regarded as being propagated by vibrations differing in direction from those of other known forms of energy. I have given expression to the view on more than one occasion that they are simply ultra-violet radiations of much greater oscillation frequency than any we have yet been able to recognise and manipulate with prisms and lenses. The following comparison of the properties of the ultra-violet with those of the Röntgen rays are my reasons for this view :—

(1) Ultra-violet rays can be reflected and refracted.
(2) They are capable of energetic chemical action.
(3) They cause fluorescence.
(4) They facilitate the discharge of electricity through air.

(1) The Röntgen rays can be reflected, but have not hitherto been refracted.
(2) They cause energetic chemical action.
(3) They cause fluorescence and also phosphoresence.
(4) They cause the discharge of electricity through a non-conductor.

The ultra-violet rays are also subject to energetic absorption, which increases with the molecular mass of the absorbing substance in certain cases, but is dependent upon molecular structure in other instances. Röntgen rays are also absorbed energetically by some substances, and the absorption appears to be dependent upon the molecular mass of the absorbing medium, but in other cases it appears to depend upon what is probably molecular structure. Both the ultra-violet and Röntgen rays are revealed to us by their action on a photographic plate and on fluorescent substances, or rather substances which they render fluorescent.

The ultra-violet rays excite fluorescence in almost all substances, and with very remarkable effects in many cases (*J. Chem. Soc.*, vol. clxiii. p. 247, 1893). The effect of substances on the rays which enter them is to retard their rate of vibration. By retardation the length of the waves is increased to dimensions which bring them within the limits of visibility, and the result is either fluorescence or phosphorescence. This is usually expressed by saying the rays are lowered in refrangibility. It is quite probable that we may soon have evidence of refraction of Röntgen rays. They are undoubtedly reflected, since Jackson has shown that the most effective form of Crookes' tube is one in which a plate of platinum at an angle of 45° reflects the rays through the side of the vessel (*Proc. Chem. Soc.*, March 6, 1896).

Röntgen rays are in all probability of the same character as the ultra-violet rays; they produce the same effects, and no other rays are known to do this, except such as are of the same character and are capable of being "lowered in refrangibility," or retarded But it is evident that they must be of much greater oscillation frequency, or what amounts to the same thing, of much shorter wave-length than any which have hitherto been studied with lenses and prisms of rock-crystal or fluor-spar.

Mr. Jackson has declared his adherence to the belief that they are propagated by transverse, and not by longitudinal, vibrations (*J. Chem. Soc.*, vol. clxv. p. 734, 1894; also *Proc. Chem. Soc.*, March 6, 1896).

I have been induced to place these remarks on record, because in NATURE (p. 45) there appears an abstract of a paper in *Wiedemann's Annalen*, by D. A. Goldhammer, which renders it evident that from other considerations he is of the same opinion. He points out that the peculiarities of Röntgen rays are not inconsistent with transverse vibrations of very small wave-length. His reference to the absence of reflection appears to be not strictly accurate, so far as one may judge from the words of the abstract; but it is not fair to draw conclusions from an author's views without regard to his *ipsissima verba*.

Analysis of Röntgen Rays.

Mr. T. C. Porter, of Eton College, appears to have made an interesting discovery in connection with the Röntgen rays, viz. that they are of at least two different kinds. We print in full a preliminary account of the experiments which have led to this conclusion, with the remark that the photographs received just as we go to press entirely bear out the description.

A Röntgen tube (Newton and Co.'s and Griffin's focus tubes have been used in these experiments) emits two different kinds of rays. To one kind, which I venture to call X_1, flesh is fairly transparent, and bone opaque; to the rays of which this is a preliminary account, which will be called hereafter X_2, flesh seems nearly, if not quite as opaque as bone. Under ordinary circumstances, in the cold, using an induction coil ($3\frac{1}{2}''$ spark) and somewhat rapid hammer contact breaker, most, but not all, of the rays are X_1; but if the tube be heated, less and less of X_1 are emitted and more of X_2 until the fluorescent screen (mine is one of Messrs. Reynolds and Branson's, of Leeds, bright yellowish green in colour, and apparently of uranium glass, though of this I am not sure) shows the shadow of a hand held behind it sharply defined and very dark all over, *the bones not being visible*. The back of the screen is covered with a layer of very opaque (to ordinary light) thick black paper. Up to a certain temperature the green fluorescence of the glass of the tube increases very markedly, but the X_2 rays do not come from it, as the sharpness of the shadow shows; nor are the X_2 rays ordinary kathode rays, for the same discharge sent through a highly exhausted Crookes' tube showing "independence" of the positive pole failed to excite any fluorescence whatever on the screen, though the glass of the tube was fluorescing brilliantly opposite the concave kathode, and the violet cone of rays within the tube was plainly visible. At a certain temperature, judging from the fluorescence on the *screen*, the emission of these X_2 rays reaches a maximum, and on further heating the emission of any rays whatever capable of exciting fluorescence or photographic action falls off rapidly, though, so far as my experiments have gone, *some* fluorescence and photographic action have been plain up to the highest temperature to which I judged it wise to heat the tube. Wood and paper seem very fairly transparent to the X_2 rays, but glass seems very opaque, aluminium much more opaque than to the X_1 rays, judging by the following experiment, which shows best the existence of these radiations and their difference from the X_1 radiations.

A "Röntgen" whole plate was wrapped in two thicknesses of the black paper generally used for the purpose, and supplied with the plates by the Sandell Plate Co., and brought in darkness into the room for experiment, lit dimly by a single candle at some distance from the place where the plate was to lie. The plate was then laid film uppermost (still, of course, wrapped in the black paper) six inches below the exhausted tube (the latter placed in the usual position). A piece of plate-glass, one-third of an inch thick, was then laid over half of it, and a left hand laid on the other half, together with a piece of a small aluminium tray, and exposure was made for one minute with the exhausted tube cold (16° C.). The paper over the exposed half was then marked for the purpose of recognition; this half was then covered with the glass, to protect it from any further action, and the photographic plate turned in its own plane through 180° about a vertical axis, to enable the operator to place his hand on the other half in exactly the same way as at first. The tube was then heated with a spirit-lamp giving a large flame for about forty-five seconds, and, the left hand being in

position, the current was switched on for one minute: at the end of this time the appearance of the discharge in the tube showing that the latter was growing cold, the current was switched off, the spirit-lamp again applied to the tube with the right hand, the operator's left hand being kept rigidly in position over the plate, then the current put on again for a minute, and so on, the spirit-lamp and current alternately, till six and a half minutes' (the current at the last time ran a minute and a half) exposure had been given. The plate was then removed and developed uncut, with a hydroquinone developer, with the result that *whilst the far denser background of the last exposed half of the plate showed that it had received by far the greater amount of radiant energy* from the heated tube during its six and a half minutes' exposure, only the very faintest traces of the bone shadow could be made out in the very bold shadow of the flesh of the fingers: and on the other half, which had received but one minute's exposure to the cold tube, images of the bones were very clearly shown. This experiment proves that the radiation received from the hot tube resemble the rays hitherto called X rays (which I have called X_1) in being able to pass through paper opaque to ordinary light, but differ from them in being unable to pass through flesh, and in other ways, an account of which must be postponed for a short time. The effect of *cooling* the X-ray tube is being investigated.

I have spoken of these rays as a new *kind* of X rays. They may be related to the X_1 rays in the same kind of way as red is related to violet light, and if so are not essentially different. Hence I could think of no better nomenclature than to retain the letter X for them, and call them provisionally X_2; but *if they have the power of penetrating aluminium at all*, they certainly act in some respects so differently from the X_1 rays, that one might feel inclined to suspect them of some greater difference than the fluorescent and photographic experiments indicate.

Plant Structure Revealed by Röntgen Rays.

Mr. George J. Burch sends the following account of experiments from the University Extension College, Reading:—

Since February 13, I have been engaged, in conjunction with my colleague Mr. Dodgson, and Messrs. Herbert, Hooper, Soper, Twiney, West and Yetts, in a series of experiments with Röntgen rays. In investigating the influence of colour upon the relative opacity of certain substances, it occurred to Mr. West to compare a purple hyacinth with a piece of purple glass which had proved remarkably opaque. I found upon development that details of the structure of the flower were distinctly visible. Following up this clue, we have photographed a number of flowers with the Röntgen rays. By suitably arranging the exposure and the development, we can show the ovules inside the ovary in an unopened bud, the seeds within a seed vessel, and even the veins upon the white petal of a flower.

Apparently these results are due to refraction and reflection of the rays when the incidence is sufficiently oblique. Similar indications are visible in a photograph of a fish's eye prepared by Mr. Yetts, in which there is a narrow dark shadow that can only be due to internal total reflection. The feathers are seen in a bird by Mr. Soper, and a foot, developed by Mr. Herbert, shows the fabric of the stocking.

I am directing the experiments with the view of photographing the soft tissues of the human body.

A Photometer for Röntgen Rays.

All those who have had occasion to use Crookes' tubes to produce Röntgen rays will have noticed the extraordinary variations in the intensity of the radiation produced by an apparently trifling change in the vacuum and the make and break of the coil. A useful step towards some quantitative measurement of the intensity of Röntgen rays has been made by M. Meslin, who, in the current number of the *Journal de Physique*, gives an account of a photometer for the rays. The principle on which this photometer depends is the matching of the brilliancy of the two halves of a circular patch of barium-platino-cyanide, one half being rendered fluorescent by Röntgen rays, and the other rendered fluorescent by the light rays proceeding from some standard source, such as a candle or lamp. The light is passed through a coloured glass, so that the fluorescence produced has the same tint as that produced by Röntgen rays. The author finds that the barium-platino-cyanide, under the influence of Röntgen rays fluoresces with a light of such a colour that the maximum brilliancy occurs for a wave-length of about $0·500\,\mu$. The barium-platino-cyanide fluoresces most strongly when exposed to light having a wave-length of about $0·460\,\mu$. By means of this arrangement the author has been able to verify the law that the intensity varies inversely as the square of the distance, the following numbers being obtained:—

Distance of photometer.	mm.	mm.	Quotient.
From luminous source	350 ...	410 ...	0·853
From source of Röntgen rays	54 ...	63 ...	0·857

The Fluorescence of Photographic Plates.

As recently stated in NATURE (*ante* p. 62), it is well known that a photographic dry plate exhibits fluorescence when Röntgen rays fall upon it. With reference to this, Mr. Shelford Bidwell believes the seat of the fluorescence appears not to be in the sensitive film, but entirely in the glass support. Writing under date May 27, he says:—

I find that bromide, iodide and nitrate of silver do not by themselves show the slightest trace of fluorescence, neither does photographic gelatine; bromide paper and coated celluloid sheets are also quite invisible under Röntgen radiation. On the other hand almost any specimen of glass will, with a good tube, fluoresce sufficiently to show coins in a purse &c.; indeed, some of the pieces that I tried happened to be more efficient than any of the ordinary dry plates that were at hand.

No doubt certain photographic plates—possibly those used by Mr. Walker—are for special purposes prepared with fluorescent substances, and it is not surprising that such should fluoresce more strongly than others.

Miscellaneous Observations.

From the *Sitzungsberichte der Kaiserlichen Wiener Akademie* we learn that Prof. G. Jaumann has investigated the deviation of kathodic rays produced by electrostatic force. The rays follow the lines of electrostatic force, and such forces produce a strong deviation in the rays. This deviation is a temporary effect, which is soon brought to an end by the lengthening of the rays. Simultaneously with this electrostatic deviation of the kathodic rays, considerable variations take place in their intensity.

The similarity between the effects of Röntgen rays and of ultra-violet light on electrified bodies, forms the subject of a paper communicated to the Academy of Bologna by Prof. Augusto Righi, in which the author considers the influence of the pressure of the gas surrounding an electrified body on the discharge of its electrification produced by these rays. It appears that, under similar conditions, the critical pressure (that is the pressure of the gas corresponding to the maximum leakage) is greater for Röntgen rays than for ultra-violet rays. But the final charge of a conductor exposed to Röntgen radiations was found by Prof. Righi to increase with diminishing pressure of the surrounding air precisely as occurs when ultra-violet rays are brought into action instead. In another paper (*Atti R. Accad. Lincei*), the same writer dissents from Prof. J. J. Thomson's opinion that every dielectric becomes a conductor when it is traversed by Röntgen rays. Prof. Righi is of opinion that it cannot be considered as proved that a *non-gaseous* dielectric is rendered a conductor when it is traversed by these rays.

While recently experimenting with a Crookes' tube, Prof. Francis E. Nipher observed that the circular aluminium disc of the kathode became slightly loose on the aluminium wire, and that it was constantly rocking in rotary motion on the wire. After several days of use, during which it had been decided to construct a tube with discs capable of rotation, the kathode disc suddenly became loosened, and began to rotate slowly on the wire as an axis. The direction of rotation was contrary to the hands of a clock, when the disc was viewed from the point where the kathode wire pierces the wall of the tube. When the loose disc was made the anode, no tendency to rotation was observed. Up to May 4, when Prof. Nipher read a paper on the phenomena before the St. Louis Academy of Science, all attempts to produce the effect in air of ordinary pressure had failed. The experiment seemed to form a basis for imposing a term representing a rotation into the equations for force and potential within a wire conductor; but in a letter received a few days ago, Prof. Nipher suggests that a circular or elliptical vibration of the kathode wire might possibly account for the rotation of

the kathode disc. The tube on which the observation was made has been cracked, and now ceases to give the result; nor is he able to impart rotation in one direction only by familiar mechanical means that could have existed in the tube.

From across the Atlantic, correspondents of some of the daily newspapers have sent vague reports of several developments of Röntgen ray work. By coating the inside of a Crookes' tube with fluorescent crystals, Mr. Edison is stated to have produced an electric lamp in which "all the energy which in an incandescent lamp is lost in heat is turned into light. One of the new lamps of only four-candle power is said to give a light equal to that obtained by the usual sixteen-candle power incandescent lamp."

A report from the electrical laboratory of the State University of Missouri states that experiment shows that Röntgen rays kill the bacilli of diphtheria. Two guinea-pigs were inoculated with a culture of diphtheria. One of them was exposed for four hours to these rays, and showed no signs of diphtheria. The other died within twenty-eight hours, and the post-mortem examination showed that diphtheria was the cause of death. It hardly needs pointing out, however, that this evidence is not sufficient to justify the conclusion.

In *Cosmos*, M. R. P. Leray gives the first portion of an article on kathodic rays and the kinetic theories of their nature. The writer points out that although recent investigations have cast some doubts on Crookes' original "radiant matter" theory, no satisfactory alternative theory has been suggested. M. Poincaré has propounded the hypothesis that the phenomenon is produced like a luminous phenomenon, but, as he remarks, this is a very strange form of light. M Leray considers that this substitution of the ether for radiant matter, while failing to account for the earlier experimental results, affords no explanation of recent discoveries. The kinetic theory should not be abandoned, simply because it does not account for all the observed phenomena, until some theory has been suggested that better accords with fact.

Finally, in the *Naturwissenschaftliche Wochenschrift*, Prof. B. R. Borggreve offers a theory of the existence of Röntgen rays, and considers particularly the relation of Röntgen's discovery to Le Bon's so-called "dark light."

THE RELIEF OF THE EARTH'S CRUST.

PROF. HERMANN WAGNER, of Göttingen, one of the best-known geographers and statisticians of Germany, has recently published in *Gerland's Beiträge zur Geophysik*, a critical study[1] of a somewhat exceptional kind. The moral of the criticism is that the agreement of the final results of a prolonged series of calculations is no proof of the correctness of the individual stages of the work, and the application is that no elaborate series of calculations should be built upon until every step has stood the test of independent verification. One is tempted to suppose that all scientific workers believed in these principles, and that the steam-hammer strokes of Prof. Wagner's ponderous criticism are really more valuable in forging a firmer structure of fact, than for the sparks of proverbial philosophy elicited by battering the work of pioneers. The solid outcome of the investigation is the most detailed calculation yet arrived at of the area and volume of the portions of the earth's crust above and below sea-level, leading to a new and interesting division of the surface of the lithosphere into regions of special morphological character. Although this comes last in the discussion, we prefer to place it first in the appreciation, because constructive work is always more pleasing to contemplate than destructive efforts, and because those who, like myself, have been somewhat severely handled by Prof. Wagner, will probably be most willing to acknowledge the superior accuracy of his results.

The question of the completeness of the data from which these results are derived, and their fitness for such minute treatment, I shall consider later.

By means of the hypsographic curve connecting elevations and percentages of area (previously employed by Penck in his discussion of Murray's data) derived from measurements of height, depth and area of land and water, the surface of the lithosphere is divided by Wagner into five regions in place of the three suggested by Dr. John Murray, and hitherto accepted by most physical geographers. The five are as follows. The *Culminating Area* of the earth's crust, occuping 6 per cent. of the surface, and lying altogether above 1000 metres, with a mean height of 2200 metres (or 7200 feet) above the sea. The *Continental Plateau*, occupying all the surface from the 1000 metre contour-line of elevation to the 200 metre contour-line of depth, *i.e.* to the margin of the shallow sea-border or continental shelf. It comprises 28·3 per cent. of the surface, and has a mean elevation of 250 metres (or 800 feet) above the sea. The *Continental Slope*, from a depth of 200 metres to 2300 below sea-level, covers 9 per cent. of the earth's surface, and has a mean depth of 1300 metres (or 4300 feet). The *Oceanic Plateau*, between the depths of 2300 and 5000 metres, occupies no less than 53·7 per cent. of the surface, and has a mean depth of 4100 metres (or 13,500 feet). Finally the *Depressed Area*, deeper than 5000 metres, is assumed to occupy 3 per cent. of the surface, with a mean depth of 6000 metres (say 20,000 feet). In this classification of regions the coast-line is ignored, the abrupt change of slope at 200 metres (or rather the familiar 100-fathom line of our charts) being rightly given the greatest weight in a hypsographic study. The mean level of the surface of the earth's crust is placed by these calculations at a depth of 2300 metres, or 7500 feet below actual sea-level. The area of the continental-block, or region above the mean level of the crust, is found to be 43·3 per cent. of the surface, leaving 56·7 per cent. for the deeper region, instead of the 50 per cent. to which my first estimate of mean-sphere-level from Murray's data pointed. Although I suggested in April 1890, the restriction of Murray's term Abysmal Area to the ocean-floor below mean-sphere-level (instead of including everything below 1000 fathoms), and to class the whole slope up to sea-level as the Transitional Area, keeping the term Continental Area for the land; I gladly recognise the importance of Wagner's new division into five zones, as shown on the accompanying curve (p. 113). Two further subdivisions might be appropriately introduced—the *Flat lands* below 200 metres of elevation, and the *Continental Shelf*, or shallow sea above 200 metres of depth. From the anthropogeographical point of view, these are the most important regions of the globe. The height of 200 metres above actual sea-level corresponds by Wagner's showing to the mean level of the physical globe (lithosphere and hydrosphere), and is thus as fitted to be a limit as is the line of mean-sphere-level itself.

The total area of land is worked out at 28·3 per cent., and that of sea as 71·7 of the earth's surface, certain assumptions being made for the unknown polar regions. The ratio of land to water surface is thus 1 : 2·54. Other interesting levels are that of the mean height of the land 700 metres (or 2300 feet) above actual sea-level; and of the condensation spheroid, *i.e.* the physical globe if the water were condensed to the density of the rocks of the crust, 1300 metres (or 4260 feet) below present sea-level.

While Prof. Wagner has sought to give more exactness to the calculations on which our knowledge of the forms of the earth's crust depends, he has shown little sympathy with any suggestions towards an explanation of terrestrial relief. We have not space at present to consider his criticism of the remarkable relations between the various natural divisions of the crust involving the ratio of the densities and volumes of land and sea pointed out by Romieux in December 1890. Similarly the strictures on Penck's "Morphologie der Erdoberfläche" may be left for that distinguished physical geographer to treat personally.

The problem of finding the areas and volumes of the portions of the earth's crust above water or covered by water, and so of arriving at some knowledge of the true forms of the earth's crust, has been attacked by several physical geographers during the last twelve years. Prof. De Lapparent, in 1883, was the first to repeat Humboldt's attempts in this direction. Dr. John Murray, in 1888, published a very elaborate calculation based on contoured maps specially prepared by Bartholomew on Lambert's equivalent projection on the scale of 1 : 45,000,000. This work was criticised on publication by Prof. Penck and Dr. A. Supan, but attained wide acceptance. Prof. Wagner, for the purposes of his well-known statistical annual, "Die Bevölkerung der Erde," had collected the best estimates of the areas of the various continents and countries, and has caused corrections and new measurements to be made from time to time. All this work may be said to depend on the measurement of

[1] "Areal und mittlere Erhebung der Landflächen sowie der Erdkruste. Eine kritische Studie insbesondere über den Anwendungsbereich der Simpson'sche Formel" Von Hermann Wagner. *Gerland's Beiträge zur Geophysik*, II. Band, 2-4 Heft (1895), pp. 667-772.

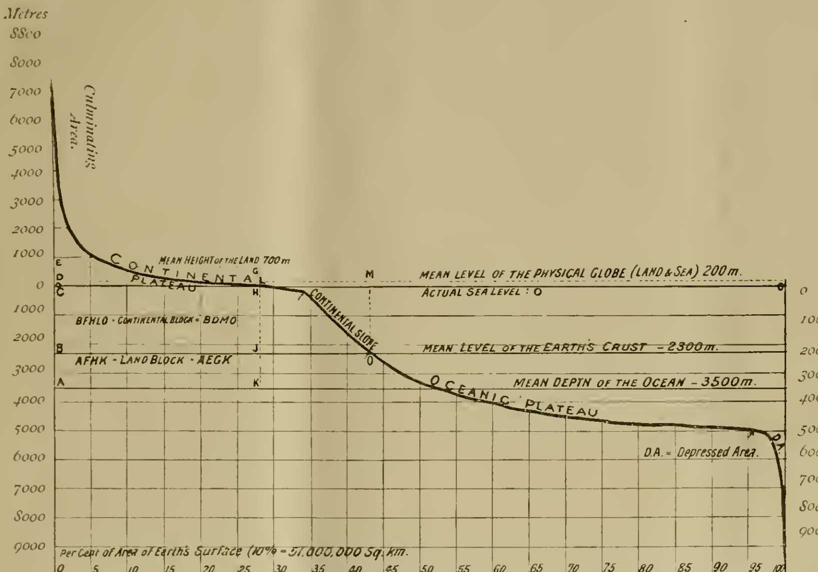
areas on maps by means of the planimeter. In 1891 Dr. Heiderich, a student of Prof. Penck's, published a series of calculations of areas and volumes of land and sea, based on an entirely different process. His method was to draw profiles of the earth's crust from contoured maps along parallels 5° apart, from the highest northern to the highest southern latitude for which data could be found. The areas of land or water for each zone of 10° of latitude wide were calculated from the length of the land or water on the three parallels 5° apart, by Simpson's formula

$$F = h/6\ (d + 4d_1 + d_2)$$

where F = the area of the zone 10° wide, h the value of the 10° interval in units of length, d, d_2 the length of the land (or of water) on the parallels bounding the zone, and d_1 the length on the parallel midway between them. Then using the *areas* of the profile above or below sea-level on each parallel, the volume of land (or of sea) in a zone of 10° is calculated by the same formula; in this case F standing for volume, and d for measured areas.

much importance. Were it not for the balancing of innumerable errors of measurement, we could not hope to gain any information at all from planimeter work on small scale maps, and no two independent measurements could possibly agree. Visible errors must of course be excluded by the exercise of all possible vigilance; but even in Prof. Wagner's critical pages there are one or two examples which show that the best intentions, the utmost vigilance, and a life-long experience of the desperate deceitfulness of proofs cannot guarantee perfect accuracy. On page 688 "II." occurs instead of "IV." in a reference to a volume, but the date being given correctly neutralises the error. On page 738 "g" should be "g_1" in referring to the mathematical formula there given, and on page 745 the expression "9,620,000 qkm. (9,000,000 + 6,200,000)" contains just such an oversight as might very seriously vitiate a calculation, the last number being obviously intended for 620,000.

The results obtained by Murray in 1888 are criticised in detail, and various sources of error pointed out. The corrections we do not hesitate to accept, but we cannot look on the original work as claiming the degree of accuracy which Wagner's criticism



WAGNER'S HYPSOGRAPHIC CURVE.

Prof. Wagner's main effort is to show the errors of Heiderich's work, first by comparison with his own new planimeter measurements, and then on theoretical grounds from the consideration of the natural difficulties introduced in Simpson's formula. In the former task Wagner was able to confirm his own estimates of the area of the land in a very neat and satisfactory way by comparison with Karsten's measurement of the oceans in zones of 10°, and he had the satisfaction of finding that the two sets of figures when added together gave a near approximation to the calculated area of the zones. The nett result of the inquiry is to show that Simpson's formula to be satisfactory must be applied to narrower zones than 10°, and that means must be taken to ensure that the intermediate values, which have four times the weight of either extreme in the final result, are really typical of the whole intermediate region. But Prof. Wagner enters into the minutest criticism of Heiderich's work, detecting errors of calculation and of typography, and showing how the use of round numbers gives rise to fresh errors in the totals. The balancing of errors which produces a fair consistency in the final result is interesting, but we believe that it receives too

implies. Had Murray's measurements been made on maps of a much larger scale, contoured at the same intervals, the results would probably have been nearer Wagner's; but we must also remember that it is the stimulus to this particular study, given by Murray's work, which has, in the ordinary course of the advancement of science, furnished his critic with data superior to those possessed in 1888.

While in several places Prof. Wagner acknowledges that his figures are only approximations, with no claims to absolute exactness on account of the uncertainty of the data, it does not appear that he realises the magnitude of this uncertainty. In the first instance measurements, even on large scale maps, are so difficult that increased precautions almost always show different results. The best example is in the case of France, where the re-measurement on the plates of the 1 : 80,000 map in 1894 showed that the area of that country was 1·48 per cent. greater than had previously been supposed. Again, it must be borne in mind that outside Europe, India, and some parts of the United States, there is not a single continental coast-line the position of which can be taken as correct. Some coast-line has to be assumed, but, except on

small-scale maps, the true position is not likely to lie within the thickness of the stroke which marks it, and deviation means change of area. Finally, we have the vast uncertainty of the utterly unknown Antarctic and Arctic regions, which are estimated by Wagner to amount to 16,000,000 and 5,000,000 square kilometres respectively, or together 4 per cent. of the whole earth's surface. In the face of all this uncertainty, does it not seem that only the balancing of errors can give an approximation to the truth regarding the areas of land and water; and that from the circumstances of the case, the fact that one set of estimates disagrees with another, independently made, is of small account? While every precaution should be taken to exclude errors of computation or of typography, it may be affirmed as a principle, that to subject uncertain data to a too rigorous discussion is waste of labour. Round figures alone can be justified for many a long day in estimating the areas of the earth's surface, and for longer still in estimating the volumes of oceans and continents.

The contour-lines on any ordinary map of a continent are only the roughest generalisation of the height, even when numerous points of altitude are fixed by exact levelling. But where a whole continent, like Africa, is measured for volume by the few barometer and boiling-point altitudes which have been taken by travellers of varying skill and in unknown meteorological conditions, the most laborious calculation can only be an elaborate guess. The temerity of the map-draughtsman in laying down the contour-lines of the oceans is justifiable as the expression of probability, not as any exact delineation. In the Atlantic they may indeed be guessed at with some confidence, but in the Pacific and Southern Oceans the mean depth might easily be hundreds of fathoms greater or less than is supposed from the scattered points which have been measured as yet.

It is right to guess at mean measurements, and to reason hypothetically from them, but there is a risk of men accustomed to critical rather than to practical work being misled against their knowledge by the firm lines of maps and the means of ingeniously grouped observations. That Prof. Wagner has obtained the best results possible by means of his calculations we recognise with sincere pleasure, but he has had the good, though naturally imperfect, work of others to start from, and a reader of his criticism might be led to disparage those workers but for whom the ambitious attempt to calibrate the earth's inequalities might have been postponed for another century.

For myself I gladly accept the new value of the mean-sphere-level as better than the avowedly rough guess which I hazarded six years ago. And although Prof. Wagner calls me "a friend of round figures," with a touch of rebuke in his tone, I shall still try to deserve the name in connection with such calculations until the improvement of geographical measurements justifies the use of decimals in percentages, and fifties of fathoms in average oceanic depths.

HUGH ROBERT MILL.

THE WORK OF LOCAL SOCIETIES.

THE practical methods of modern biological research have been developed to such a high state of perfection since the introduction of the appliances of physics and chemistry, that the system of training in biology has within a comparatively short period undergone a complete revolution. As one result of this change the student is tempted from the fields and hedgerows, from the downs, heaths and woodlands, from the banks of streams, and from the sea-shore into the laboratory. He knows the structure of a certain number of "types," but he walks as a stranger among the living animals and plants that surround him. His knowledge is not of that kind attributed to the wise king who "spake of trees, from the cedar-tree that is in Lebanon, even unto the hyssop that springeth out of the wall: he spake also of beasts and of fowls, and of creeping things, and of fishes." The organism is to the modern student not a living entity having a beautifully adjusted relationship to its environment, but a complicated collection of tissues capable by appropriate treatment of being spread out into a panorama of thin slices. His acquaintance with the living plant or animal is of about the same kind as that which a chemist ignorant of mechanics would acquire by endeavouring to understand the working of a watch by making a chemical analysis of its wheels and springs. In brief, the extreme specialisation of laboratory work begins too early in his curriculum. Since the introduction of the system of instruction by "types," there has arisen an estrangement between the old school of field naturalists and the modern biologist—a result which was not anticipated by the founders of this system, and against which a healthy reaction, led by Mr. Thiselton-Dyer and others, is beginning to take place.

It is true that certain departments of biology have gained enormously by the introduction of modern methods, and it must also be admitted that some branches, such as morphology and physiology, are best dealt with in laboratory and dissecting-room. But at the same time it is to be deplored that the department which Prof. Ray Lankester has happily termed "bionomics" should be allowed to suffer by competition with the new methods. If biology has gained in some directions, it is certainly the case that as a subject for the scientific training of the observing faculties, it has suffered deterioration by leaving the field naturalist outside the pale. The latter, finding himself threatened with scientific excommunication, is driven into the pages of popular magazines, or writes books which, although often very pleasant reading, are painfully sterile from the purely scientific point of view, and most disappointing when the capabilities of the writers are taken into consideration. Between the cabinet systematist who studies nature in museums, on the one hand, and the laboratory worker, who ignores the animal or plant as a living organism, on the other hand, the student of the old school of natural history is being hard pressed to find a footing. In a country like ours, with its immense colonies and dependencies in every quarter of the globe, it is most regretable that our educational authorities do not recognise field natural history as a subject worthy of their most serious encouragement.

While the modern development of biological teaching has led to the result above indicated, the local societies of this country have, in an unpretending way, been doing good work by keeping alive the spirit of the old school of naturalists. There are now on the list of Corresponding Societies of the British Association sixty-three societies distributed over the United Kingdom.[1] All of these are more or less actively engaged in carrying on local observations in various fields of science, and their very existence is good evidence that there is a store of available energy in this country which is by no means a negligible quantity in estimating the scientific status of the nation. Field natural history forms a large part of the work of these societies, and this is certainly one of the directions in which every encouragement should be given by all who are interested in their welfare. Under field natural history would be included the collecting and recording of species so as to furnish materials for the compilation of local faunas and floras, observations on the habits and life-histories of individual species, the systematic recording of dates of appearance of species, &c., comprised under the general subject of phenological observations. The local societies have already done much work in these subjects, and much more remains to be accomplished. In connection with the collecting of specimens it might be well to point out that these societies can do an enormous service by discouraging on every occasion the unnecessary destruction of life—by teaching by precept and showing by example that the mere acquisition of specimens is not the end and aim of natural history work, and that when a typical collection has once been formed the needs of science have been met. Most particularly is the assistance of the local societies wanted in protecting the "lower orders" of the animal kingdom and the rare species of plants from the depredations of the "dealer" or the avarice of the collector, for while our birds are now likely to flourish under a beneficent Act of Parliament, it is impossible to make a public appeal to the argument from sympathy with sentient beings in the case of the invertebrate classes of animals, or in the case of the rare plants which still linger in unfrequented districts. These are cases fo appeal to scientific reason rather than to sentiment. Is it too much to hope that the societies in each district should approach the landowners on whose estates rare species are know to occur, and invite them to co-operate in securing the protection of our choicest forms of animal and vegetable life?

In many other directions is there scope for useful scientific work on the part of local observers.[2] In geology, for instance,

[1] The total number of members registered as belonging to these societies is nearly 24,000. It is of course difficult to arrive at the actual numbers, because the same member may belong to more than one society; but after making every allowance for such repetitions, it will be seen that the volunteer army of scientific workers is much stronger than has hitherto been realised.

[2] For some valuable suggestions with respect to meteorological work, see the address to the Conference of Delegates at the last (Ipswich) meeting of the British Association, by Mr. G. J. Symons, F.R.S., Chairman of the Conference.

temporary sections are often exposed, which a resident in the district might take the opportunity of sketching or photographing and describing while the chance is open to him. Such opportunities are frequently lost owing to the temporary character of the work which has necessitated the excavation, and the absence of a qualified observer at the right time. It cannot be made too widely known to the members of local societies that every extensive artificial excavation is worth calling the attention of geologists to, and particularly when the society comprises no geological expert in its own ranks, because external aid might then be solicited before it is too late.

There are also certain special lines of geological work in which local co-operation has been found of great value, such, for instance, as the recording of the rate of erosion of sea-coasts, the distribution, mode of occurrence, mineralogical characters, &c., of erratic blocks, the height of water in wells, and so forth. These investigations have been, or still are being, carried on by British Association Committees, and are mentioned here simply as illustrations of the kind of work in which the members of local societies might take part. In anthropology and prehistoric archæology there is also abundant scope for local effort in the way of registering ancient remains, conducting systematic explorations, and assisting in their preservation by the appointment of vigilance committees. The needs in this department of science have been set forth in the reports of the British Association Ethnographic Survey Committee, and have from time to time been referred to in these columns in the reports of the conferences of delegates of Corresponding Societies.[1]

Thus, while there is plenty of work for local observers to do, and while the efforts which have been made in the past, and which are still being made by the provincial societies are worthy of the highest commendation, it cannot be denied that the energies of our local workers are not altogether as productive as they might be made for the cause of science. To point out a few of the reasons why the scientific activity of local societies is not producing the best possible results in the way of original investigation, may go some way towards suggesting remedies. In the first place, there is very frequently a want of co-operation between workers in the same or in neighbouring districts. This leads to a frittering away of energy by several people doing the same thing independently and unnecessarily. Such want of co-operation often arises from petty local jealousies which, however contemptible, may be powerful enough to cripple progress. Perhaps the best way to ensure co-operation is to bring the societies of the same or neighbouring counties into occasional intercourse by means of a system of federation. The Unions of naturalists' societies, such as those of Yorkshire, the Midlands, and the East of Scotland, have done good service in this way. As we have already announced, a Congress of Societies of the South-east of England was held at Tunbridge Wells on April 25. On a wider scale the British Association has for the last eleven years been giving facilities to the representatives of local societies all over the country for meeting and holding annual conferences under the official auspices of the Association. Not the least important feature of these conferences, which are regularly reported in these columns, is the opportunity which they give the delegates of learning directly from scientific experts the particular lines of work in which local co-operation is likely to be of real value to science. The work of some of the Association Committees has in this way received considerable local support, but on the whole the assistance given is not as great as could be wished. It may be useful to attempt an analysis of the causes why such aid has not been more freely rendered.

Any one who looks into the publications of local societies, or who is acquainted with the details of their management, must become impressed with the fact that the greater part of the work is done by amateurs. We do not use this term in a disparaging sense; on the contrary, it redounds to the credit of this country that so much work should be done by amateurs. But the workers of this class, however enthusiastic, are often devoid of scientific training, and are still more generally prevented by other occupations from carrying on continuous observations in any one subject. Hence the sporadic character of the work published, the want of co-ordination, and the difficulty of getting adequate assistance for the systematic recording of observations required by the prolonged inquiries undertaken by the British Association Committees. Another weakness which the amateur often possesses is the tendency to cope with too wide a range of subjects, and a desire to take in hand the whole circle of the sciences rather than devote himself to the drudgery of detailed observation in one limited field. Much good would result if it could be brought home to those who really desire to further the cause of science by local work, that the united efforts of a number of workers, each labouring in his own little domain, is in the long run the best of all methods for advancing knowledge by original contributions. If the amateur would curb his ambition, and take counsel with his co-workers, the volumes of some of the publications which have come under our notice would shrink in size, but the literature of science would gain considerably thereby.

The most promising remedy for these and other defects which are incidental to associations composed of more or less fluctuating elements appears to be the system of federation, if it can only be effected practically so as to over-ride the petty local narrowness which so frequently prevails. By co-operation the general level of the work done would be raised; it would be made more obvious to each worker that the cause of science is the one determining influence that should bind together the members of the society and the society to the Union. Numerous other advantages would naturally follow the adoption of such a course. Not the least important of these is the improved status which each society would gain by being affiliated with its neighbours. If the status is raised more support might be looked for from the wealthy county residents, who, although not themselves personally concerned with scientific work, might feel it a duty to encourage the county society. It may be pointed out incidentally that one of the most frequent causes of the collapse of local societies is the want of pecuniary support. This at least is the proximate cause; but the ultimate cause in such cases is as often as not the diminishing activity of the society itself, and the consequent loss of interest in its proceedings. It is confessedly difficult to keep up continuous active interest among such fleeting associations of members as compose the rank and file of the local societies. Many join at the foundation, carried in by a wave of temporary enthusiasm which soon dwindles down to an evanescent ripple, ending in the dead calm of indifference and ultimate secession. Or, again, the officials who float the society with all the enthusiasm of novelty may leave the district, or, worse still, kill the creation of their youth by the decrepitude of old age, and by tenaciously holding office convert the association into "a one man society" with a fossilised official for its executive. Truly it has been said that a local society is just what its secretary likes to make it. With federation and co-operative action there would arise a stimulating influence tending to prevent the decline of any one of the federated societies through these or any other of the thousand natural causes that affect the healthy existence of such associations. There would also be added to these beneficial effects an increased element of stability and permanence, more particularly if the societies constituting the federation were bound together by having one common publication. With respect to this last suggestion, there is everything to be said in its favour from the point of view of economy, from the point of view of avoiding the unnecessary duplication of editorial work, and, not least, from the point of view of diminishing the amount of printed matter which the scientific reader is now supposed to assimilate.

Many other aspects of the work of local societies might have been dwelt upon with advantage, but this want of centralisation appears to be one of the chief causes why their scientific productiveness is not commensurate with the number of workers scattered throughout the country. We should like to see the whole of the British Islands parcelled out into groups ot counties, each group being represented by a federation of all the societies contained in the counties composing the group. Such Unions are wanted, for example, by the South Eastern, the South Western, and the Western counties, as well as by East Anglia and other naturally associated groups of counties which will suggest themselves. The formation of these Unions would not only strengthen the societies already in existence, but would lead to the establishment of other societies in districts that were not already provided for. There is no reason why, in view of all the available scientific energy which is known to exist, the local society should not become a real power in each district—a centre of intellectual enlightenment worthy of public recognition and support in the same sense that every other

[1] See an article by the writer, in NATURE, vol. xxix. p. 19 (1883).

county institution has a claim upon the county residents. The foundation and maintenance of local museums is distinctly a part of the work of the local societies; in so far as these museums can be utilised for educational purposes, they have a claim to support from the County Councils, and in a few cases such support has actually been given. We note with satisfaction that the London County Council in the estimate for the expenditure by its Technical Education Board for the ensuing year has allocated a certain sum to "museums." The county of Essex is, we believe, unique in having attached to its Technical Instruction Committee a certain number of representatives of the local society. In agricultural and maritime districts where technical instruction centres round the sciences which are more particularly cultivated by the local societies, there is no reason why there should not always be co-operation between these societies and the County Councils. If such co-operation is at present the exception rather than the rule, it is because the local societies have not made their influence as intellectual powers felt with sufficient force. Let these societies knit up their scattered units, let their amateur workers be educated up to the necessity for carrying on systematic instead of casual observations, let them court the respect to which their labours entitle them by putting forth good evidence of activity, and they may play a far greater part in the scientific development of this country than has hitherto fallen to their lot. R. MELDOLA.

CAMPHOR.

CAMPHOR is not the exclusive product of any one natural order, genus, or species; but what is more remarkable, of closely allied species of camphor-yielding genera—one species possesses the secretion, while no trace of it is found in another. Although several kinds of camphor are articles of commerce, little, if any, reaches this country, save that obtained from *Cinnamomum camphora* (*Camphora officinarum*), a member of the laurel family, and of the same genus as the tree whose bark furnishes the spice called cinnamon. Like many other natural products of which scientific research has multiplied the applications, camphor is becoming dearer and scarcer, and the question has arisen, How is the supply to be maintained equal to the demand? The bulk of the camphor imported into Europe comes from Japan and Formosa, and comparatively little from China. This is the product of *Cinnamomum camphora*, and Dr. E. Grasmann has published [1] an interesting account of this tree, both from a scientific and commercial standpoint. He has rather overweighted his article with second-hand information respecting laurels generally and those of Japan in particular, which, as might be expected, is inaccurate in some details. Disregarding these, we find much that is interesting concerning the camphor-tree itself, which is one of the noblest objects in the forests of eastern sub-tropical Asia. It attains gigantic dimensions, surpassing all other trees of the Japanese forests, at least in girth of trunk if not in total height. Dr. Grasmann gives the recorded dimensions of various notable trees, but what is more to the point, he also gives measurements made by himself. A tree in the neighbourhood of the town of Miyazaki, Oyodomura, measured in 1894, was 14·80 metres in circumference at 1 30 m. from the ground, or 4 48 m. in diameter, and it was 35 m. high. There is an illustration of this giant reproduced from a photograph. Concerning the distribution of the camphor-tree in Japan, the author states that it grows naturally in Kinshin up to about 34° lat., and scattered in favourable situations some 2° farther north, the extreme limit being 36° 24′. It is abundant in the island of Formosa, and also occurs in the Tsusima and Luchu groups. On the mainland of China, according to Dr. Grasmann, it inhabits the coast region from Cochin-China to the mouth of the Yangtzekiang, and it may be added that it is now known to extend westwards at least as far as Ichang in the central province of Hupeh. From Dr. A. Henry's notes accompanying his specimens in the Kew Herbarium, it appears that the wood is in great request, but no camphor is extracted: and Consul Playfair reported the same from Pakhoi, Kwangtung, in 1883. Indeed the camphor industry would seem to be at present very limited in China, although the tree is common and widely spread. The little that is exported is mostly from the province of Fokien, but the amount is increasing in the same measure as the production is decreasing in Japan. In the latter country something has been done to maintain the supply, but Dr. Grasmann holds that the present rate of planting is wholly inadequate. He urges the importance of increasing the plantations to the greatest possible extent, inasmuch as every part of the tree is useful, from the roots to the young shoots and leaves. Even the fruit is employed in the preparation of tallow. In Formosa camphor distilling has been carried on in the most recklessly extravagant manner imaginable. It is suggested that Japanese rule in the island may put a stop to such disastrous waste.

With regard to the increasing price of camphor, it has been stated in various publications that this is due to its being used in the manufacture of smokeless powder. In reply to inquiries on this point, Sir Frederick Abel wrote to the Director of Kew in November last as follows:—

"Any increase of demand, involving a rise in the price of camphor, is not due to its application as a constituent of smokeless powder. That material was used in the earliest days of the manufacture of a successful smokeless powder for artillery and small arms; but its employment was soon demonstrated to be attended with serious practical disadvantages, and its application for the purpose can therefore not be said to have been other than experimental, and of no great importance, even at that time, as affecting the market value of camphor. This substance has, however, been used extensively for many years past, and no doubt in continually-increasing quantities, for the conversion of collodion cotton into the material known as celluloid, which is applied to the manufacture of imitation ivory, tortoiseshell, horn, and a great variety of purposes."

As Dr. Grasmann observes, the greatest enemy of the camphor-tree is man, and in Japan large trees are eventually killed through the felonious nocturnal grubbing of their roots. Some birds are fond of the fruit and seed, and the caterpillar of *Papilio sarpedon* feeds on the leaves; but, except to young plants, they cause comparatively little damage. Apart from the wanton destruction of trees, the probability of the supply of camphor being maintained is seriously diminished by the fact that the tree grows but slowly in its early years. At the same time it colonises freely, and is now naturalised in several countries, notably in Madagascar, where, according to Dr. Meller, in a note accompanying a specimen in the Kew Herbarium, it was abundant as long ago as 1862, and was much used for building purposes.

Next in point of importance in producing camphor is *Dryobalanops aromatica*, a tree belonging to the Dipterocarpeæ, and inhabiting Borneo and Sumatra. The formula of ordinary camphor is $C_{10}H_{16}O$; of Borneo camphor, $C_{10}H_{18}O$; and the latter can be artificially prepared from the former. Borneo camphor is deposited in clefts and hollows of the wood, and has simply to be taken out; but it is comparatively rare, and exceedingly dear, bringing eighty times more, according to Grasmann, than ordinary camphor. Nearly the whole production is imported into China, where it is esteemed beyond the ordinary camphor, and used as incense.

Blumea balsamifera (Compositæ), a shrubby plant exceedingly common in tropical Asia, yields a kind of camphor by distillation. Hainan is the principal seat of the industry, but the crude article is refined at Canton, whence there is an annual export of about 10,000 pounds. No doubt this source of camphor could be much more extensively utilised.

Members of various other natural orders, notably the Labiatæ, yield essential oils of the same composition, and having the same properties, as camphor. Menthol is an example.

W. B. H.

URANIUM.

THE introduction of the electric furnace by M. H. Moissan as an instrument of research, has opened up many new fields of work; among which the preparation of those metals whose oxides had been looked upon as irreducible by carbon, is not the least interesting. Three years ago the metal uranium was obtained in this way, and in a recent number of the *Comptes rendus* (May 18), M. Moissan gives a more complete account of the preparation and properties of this metal. The metal was isolated by three methods, by the action of sodium at a red heat upon the double chloride of sodium and uranium, $UCl_4 . 2NaCl$,

[1] "Der Kampferbaum. Mittheilungen der deutschen Gesellschaft für Natur- und Völkerkunde Ostasiens in Tokio," vi. pp. 277-315, with illustrations. 1895.

the electrolysis of this double salt in the fused state, and from the oxide, by reduction with carbon in the electric furnace. All three processes give good yields, the last-mentioned being the best, if care be taken not to unduly prolong the heating in contact with carbon, and to exclude air.

Metallic uranium, when pure, is perfectly white, and is not magnetic if free from iron. It is not hard enough to scratch glass, takes a good polish, and can be filed with ease; in the electric forge it is much more volatile than iron.

M. Henri Becquerel, in the same number of the *Comptes rendus*, gives an account of a remarkable property of this metal, which appears to be unique, that of emitting invisible phosphorescent rays capable of producing photographic effects after traversing opaque bodies such as cardboard, aluminium, copper, and platinum, and also able to discharge a gold-leaf electroscope. The effects produced are precisely similar to those previously obtained from uranium salts, such as potassium uranyl sulphate, except that they are nearly four times as intense. The chemical behaviour of uranium depends to a certain extent upon its state of division. The metal obtained by electrolysis, which is finely divided, takes fire in fluorine, is attacked by chlorine at 180°, by bromine at 210°, and by iodine at 260°, the reactions in all cases being complete. The powdered metal is completely burned in pure oxygen at 170°, and decomposes water, slowly at the ordinary temperature but more quickly at 100°. Uranium must be added to the rapidly increasing group of metals which combine directly with nitrogen at high temperatures. Fragments of the metal heated to about 1000° in a current of nitrogen become covered with a yellow layer of nitride, and hence in the preparation of the metal it is necessary to work in such a manner as to completely exclude air.

SCIENCE IN THE MAGAZINES.

THE celebration of the Kelvin jubilee at Glasgow on June 15–17, makes the appearance of an article on the renowned investigator, in the June number of *Good Words*, very opportune. The author is the editor, Dr. Donald Macleod, once a student of Lord Kelvin's, and his description of the master is a most appreciative one. Illustrations of Glasgow University, Lord Kelvin's class-room, laboratory, and study, and of Lord and Lady Kelvin, give additional interest to the article.

An excellent illustrated article on "The Rise of the Royal Society," is contributed to the *Leisure Hour* by Mr. Herbert Rix, the late Assistant Secretary of the Society. Other articles of scientific interest in the same magazine are "Notes on the Zoo," by Mr. W. J. Gordon, with illustrations from photographs by Mr Gambier Bolton; "The New South Africa," by Mr. Basil Worsfold; and "Modern Hygiene in Practice," by Dr. A. T. Schofield.

Science Gossip contains the first of a series of articles upon the scientific worthies at the National Portrait Gallery, illustrated with sketches of the pictures by Miss J. Hensman. We understand from the article that there are about thirty portraits of scientific men out of upwards of a thousand pictures in the Gallery.

An article on Africa since 1888, with special reference to South Africa and Abyssinia, by the Hon. Gardiner G. Hubbard, and accompanied by a striking portrait of the author, appears in the *National Geographic Magazine* (May). Another paper on Africa, "Impressions of South Africa," is contributed to the *Century Magazine* by Mr. James Bryce, M.P. In the *Contemporary*, there is an article by Dr. George Harley, F.R.S., on "Champagne," having medical as well as gustatory points of interest. *Good Words* has an article on "Aluminium," by Prof. Jamieson, and on "Flowers of the Forest," by Mr. Edward Step. Mr. W. H. Hudson has an article on "Ravens in Somersetshire" in *Longman's Magazine*. Among the popular articles in *Chambers's Journal* is one on "Photography in Colours," descriptive of Mr. Ives' process, and another on the Harvey process for hardening steel. Sir Robert Ball describes the planet Saturn in the *Strand Magazine*. Students of animal life may be interested in the second paper on "The Evolution of the Trotting Horse," contributed by Mr. H. Busbey to *Scribner*.

In addition to the periodicals mentioned, we have received the *Humanitarian*, *Fortnightly*, and the *Sunday Magazine*, but no articles in them call for notice here.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MR. H. J. HEINTZ has given 10,000 dols. to the Kansas City University, the corner-stone of which has just been laid.

THE Technical Instruction Committee of the Middlesex County Council have decided to offer a scholarship, worth £50 per year for two years, tenable at the City and Guilds of London Institute. This scholarship is to be competed for by boys to whom scholarships at secondary schools were awarded in 1893. It is to include school fees, railway fares, and maintenance.

THE following are among recent announcements:—Dr. Otto Fischer to be Extraordinary Professor of Mathematics in Leipzig University; Prof. L. M. Underwood to be called to the chair of Botany in Columbia University; Dr. George A. Dorsey to be Curator in the Department of Anthropology in the Field Columbian Museum at Chicago; Dr. Franz Boas to be Lecturer on Physical Anthropology in Columbia University; Prof. Harold B. Smith to be Professor of Electrical Engineering in the Worcester Polytechnic Institute.

FOR news of the following gifts to education and research in America, we are indebted to *Science*:—Mr. Thomas McKean has offered to give 100,000 dols. to the University of Pennsylvania upon condition that 1,000,000 dols. be collected. Mr. McKean, who is a trustee and an alumnus of the University, gave 50,000 dols. about a year ago.—Mr Charles M. Dalton has given the Massachusetts Institute of Technology 5000 dols. for a scholarship in chemistry for graduate students. Preference will be given to those undertaking chemical research applicable to textile fabrics.—Real estate and securities valued at 215,000 dols. have been presented to the North-western University by William Deering, of Evanston, who had previously given the University about 200,000 dols.

WE have to record another attempt to divert part of the funds available under the Local Taxation (Customs and Excise) Act, 1890, to the General County Fund. This time it is the Isle of Ely County Council. At their meeting held at March, on May 20, it was proposed "that £1000 of the Imperial grant be allocated to the General County Fund, instead of the £150 recommended by the Committee." The proposal was eventually rejected, it is true, but only by a majority of two in a meeting of forty. The argument which was used in the North Riding County Council a short time ago, and to which we called attention, was again repeated—that it was never the intention of Parliament for the whole of these funds to be devoted to the purposes of technical education. No stronger reason than such occurrences as these could be found for the necessity of the provision in the Education Bill that these funds must be devoted to educational purposes.

WE are glad to learn from *Science* that an effort is now under way in connection with the National Educational Association to bring about greater interest in the *teaching* of science than has hitherto been shown by American botanists, zoologists, chemists, physicists, &c. The new Department of Natural Science Instruction is intended to bring together the teachers of the natural sciences who are interested in science *as a means of culture*, and to stimulate thought and discussion as to how this end may best be obtained. What *rôle* should botany, zoology, chemistry, physics, &c., play in the mental development of man? In what way may the study of plants, animals, chemical compounds and physical forces be made an efficient factor in a man's mental training? When and how shall such study be made a part of a man's training? These are some of the questions which will be discussed in the Department of Natural Science Instruction in the Buffalo meeting of the National Educational Association, on Thursday and Friday afternoons (July 9 and 10).

THE Technical Instruction Committees of the Oxfordshire County Council have decided to devote £560 to scholarships during the next year. Of this amount £294 will be absorbed on account of the scholars already elected. The balance is to be devoted to further developing the scholarship scheme. Amongst other arrangements, we notice that it is proposed to elect three sons of tenant farmers to County Council scholarships of an annual value of £15. The candidates must have been under fourteen years of age on December 31, 1895, and must have lived in the county for two years previously. The scholarships will be held at Burford Grammar School for the first two years. Sums of £366 and £314 have been respectively allotted for capitation

grants and rural agricultural instruction. The programme for the year also makes the following provisions:—For dairy instruction, £250; for manual instruction in woodwork, £228; for nursing, ambulance, and general hygiene, £190; for dressmaking, £100; for instruction in poultry-keeping, £35; for hedging and thatching, £25. We are very sceptical as to the wisdom of so diffuse a syllabus of work, and would again point out that no efforts should be spared to coordinate and systematise all the educational projects of a County Committee.

A PROSPECTUS referring to the Faculty of Applied Science of McGill University, Montreal, announces that, through the munificence of Mr. W. C. McDonald, a Department of Architecture has been established in the Faculty, and the regular work of the new department will commence with session 1896-97. During the summer, a Professor of Architecture is to be appointed, and the efficiency of the Drawing Department is to be much increased by the addition of a lecturer in freehand drawing and descriptive geometry. The same benefactor has also rendered it possible for the University to place the Departments of Chemistry and Mining in a thoroughly efficient condition. The erection of a large building is to be proceeded with immediately, and the building will be equipped in the most approved manner, including not only provision for the several branches of chemistry, but also for mineralogy, mining, and metallurgy. The Mining and Metallurgical Laboratories alone will have a floor space of about 10,000 square feet, and will be supplied with the most recent appliances for the milling and metallurgical treatment of ores, &c. A Professor of Mining will be appointed during the summer, and other important changes in the staff, all leading to increased efficiency, are to be made.

SCIENTIFIC SERIALS.

Symons's Monthly Meteorological Magazine, May.—The worst gale of the nineteenth century in the English midlands. This storm occurred on March 24, 1895, and has not been fully discussed, although some local scientific societies have published short papers upon it. The present number contains part of the list of damage done in various countries; in the next number it is proposed to complete it, and to offer some general remarks upon the subject. Mr. Symons considers that the damage done is without parallel since "the great storm" of 1703. It is a curious coincidence that it occurred on the same day of the year, and nearly at the same hour, as that of the *Eurydice* squall in 1878, in which, it will be remembered, Her Majesty's ship was lost. This latter storm was discussed by the late Mr. W. C. Ley.—Fog, mist, and haze, by "F. R. Met. Soc." In the hope of initiating a discussion upon the existing absence of unanimity as to the meaning attached to the different words in general use, the author has suggested certain definitions, which are briefly as follows:—Fog; an obscuration due to condensation of aqueous vapour when the particles are too small to be seen with the naked eye. Mist; when the particles are large enough to be seen with the naked eye. Smoke-fog; obscuration without water particles. Haze; an obscuration of distant objects, so slight that the cause is not visible to the observer.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, May 7.—Mr. A. G. V. Harcourt, President, in the chair.—The following papers were read:—Carbon dioxide, its volumetric determination, by W. H. Symonds and F. R. Stephens. The authors describe a trustworthy method of estimating carbon dioxide in air.—On certain views concerning the condition of the dissolved substance in solutions of sodium sulphate, by R. F. D'Arcy. Experiments on the viscosity of strong solutions of sodium sulphate confirm the generally accepted view that the condition of sodium sulphate in aqueous solution is always the same, whether the solutions are prepared from the anhydrous salt or one of its two hydrates.—Luteolin, II., by A. G. Perkin. The results of the further examination of luteolin are given; it is isomeric with fisetin, and probably has the constitution

$$\begin{array}{l} \mathrm{C(OH).CH{:}C.CO - C.C_6H_3(OH)^2} \\ \| \qquad\qquad | \qquad\qquad \| \\ \mathrm{CH.C(OH){:}C.C(CO).CH} \end{array}$$

.—Morin, Part I., by H. Bablich and A. G. Perkin. Morin, a yellow colouring matter occurring in old fustic and in Jackwood, is isomeric with, and has a very similar constitution to quercitin.—Synthesis of pentacarbon rings. Part I. Anhydracetonebenzil and its homologues, by F. R. Japp and G. D. Lander. Anhydracetone benzil has been fully investigated, and is shown to be a diphenylhydroxycyclopentane of the constitution

$$\left.\begin{array}{l} \mathrm{CPh - CH} \\ | \\ \mathrm{CPh(OH).CH_2} \end{array}\right\rangle \mathrm{CO}.$$

—Synthesis of pentacarbon rings. Part II. Condensation of benzil with acetonedicarboxylic acid, by F. R. Japp and G. D. Lander. The behaviour towards reagents of anhydracetonebenzilcarboxylic acid, which is obtained by the condensation of benzil with acetonedicarboxylic acid, is described.—Reduction of desyleneacetic acid, and the constitution of Zinin's pyroamaric acid, by F. R. Japp and G. D. Lander. Desyleneacetic acid yields Meyer and Oelker's desylacetic acid on reduction and $\beta\gamma$-diphenylbutyric acid on boiling with hydriodic acid and phosphorus; this acid is identical with Zinin's pyroamaric acid.—Electrolysis of potassium allo-ethylic camphorate, by J. Walker and J. Henderson.—Flourene and acenapthene, by W. R. Hodgkinson. The red substance obtained by the oxidation of flourene and acenaphthene is not a hydrocarbon, but contains oxygen; no coloured hydrocarbon can be prepared by oxidising these substances.

Mathematical Society, May 14.—Major MacMahon, R.A., F.R.S., President, in the chair.—Mr. H. F. Baker spoke upon the bitangents of a plane quartic curve and the straight lines of a cubic surface.—A paper by Prof. E. W. Brown, on the application of the principal function to the solution of Delaunay's canonical system of equations, was taken as read.—Short communications were made by the President, Colonel Cunningham, Prof. Hill, F.R.S., Mr. Hammond, and Mr. Tucker.

CAMBRIDGE.

Philosophical Society, May 11.—Prof. J. J. Thomson, President, in the chair.—Note on the formation of the layers in Amphioxus, by Mr. E. W. MacBride.—Note on the continuity of the mesenchyme cells in Echinoderms, by Mr. E. W. MacBride.—Mr. F. C. Shrubsall read a paper on crania from Teneriffe, embodying the measurements of sixty-one skulls and two hundred long bones. The average height of the islanders, calculated from the latter, was for males 1642 mm. and for females 1552 mm.

EDINBURGH.

Royal Society, May 18.—Prof. Chrystal in the chair.—Mr. W. G. Robson, St. Andrews, exhibited some X-ray photographs, and described the progress of the study at St. Andrews University. Some of the exposures were long compared with what has been done recently, notably by Dr. Macintyre: but the photographs were all very good, and the definitions remarkably clear. Some of the pictures shown were very interesting. A photo of a mummy's foot was exhibited, and Mr. Robson remarked that the rays must have had some effect on the skin, for, at the end of the experiment, it was found to be quite soft. A photograph of what looked at first sight like some insect, but turned out to be a St. Andrews "bulger" with the lead showing very clearly, caused some amusement. Prof. Chrystal thought that uranium would be of great use in intensifying X-ray photographs.—Prof. D'Arcy Thompson made a short preliminary communication on the bird and beast names in Albertus Magnus. There were very many barbarous-looking names for beasts and birds in Albertus Magnus, which have a certain resemblance to words in Aristotle. The Dominican friar did not know Greek, but used an Arabic translation of Aristotle. If the Greek words were transliterated into Arabic, they were found to be parallel with the words used by Albertus when treated in the same way.—Prof. Thompson also read a paper on the Σ of Diophantus. Diophantus used Σ for an unknown quantity. Most commentators take this to be the *s* of *ἀριθμός* ("*ὁ ἀόριστος ἀριθμός*"), but there are difficulties attached to this interpretation. Sometimes the Σ has the sign of the genitive or plural written in small letters beside it, pointing rather to the fact of its being an initial letter. Prof. Thompson suggested *σωρός*, a heap, connected with the heap-calculus of the Egyptians, and gave various reasons for his suggestion. If true, this hypothesis, in linking Diophantus on to the Eastern culture, deprived him of his position as the father of mathematics, and helped to prove that many of his problems, as was conjectured long ago by Morgan and Bonnycastle, were not original but were collected from

Egyptian mathematicians.—Prof. Thompson next communicated a paper by a pupil, W. T. Calman, on the affinities of the genus *Anaspides* to certain fossil Crustacea. Mr. Calman's re-examination of this remarkable fresh water schizopod from Tasmania has resulted in the discovery of certain important features not observed by its discoverer, notably the presence of what appears to be a group of ocelli on the dorsal surface of the cephalic region. The significance of this, and other morphological peculiarities, was discussed at length, and the indications of divergent affinities with Decapods, Edriophthalmates, and other groups were pointed out. Finally, it was shown that *Anaspides*, while not closely comparable with any living crustacean, possesses strong resemblances to certain Palæozoic crustacea forming the groups *Syncarida* and *Gampsonychidæ* of Packard, whose systematic position has hitherto been a complete puzzle to palæontologists.—Prof. Tait indicated the nature of his paper on the linear and vector function, and promised to give it in detail at an early date.

DUBLIN.

Royal Dublin Society, April 22.—Prof. Grenville A. J. Cole in the chair.—Mr. J. R. Kilroe read a paper on the distribution of drift in Ireland, in its relation to agriculture. The relation between the drift and the underlying rocks was discussed, and the general mode of origin and succession of the glacial deposits in Ireland were described. The importance of considering the stones included in sands or clays as sources of fertilising materials was especially dwelt on, and illustrations were given of the physical and chemical constitution of numerous Irish drift deposits. A broad system of separation of the constituents was adopted, such as would be suited to agricultural requirements.—The following abstract of a paper by Prof. T. Rupert Jones, F.R.S., and Mr. J. W. Kirkby (communicated by Prof Sollas, F.R.S.), on the Ostracoda of the Carboniferous Formations of Ireland, was read March 18, but was not in time for publication in the report of that meeting sent to NATURE. In 1866 Messrs. Jones and Kirkby made a critical examination of all that had been published about the Carboniferous Entomostraca (Ostracoda) of Ireland, in the *Annals and Magazine of Natural History*, ser. 3, vol. xviii., pages 37–51. Having in the interval from 1866 received numerous species of Ostracoda (Podocopa) from the Carboniferous Formations of Ireland, the authors have put them, together with those already tabulated and described, in a convenient arrangement, so that geologists, and naturalists in general, should be able to form their judgment on this branch of the Palæontology of Ireland. Many of the specimens have been treated more or less fully in some of the authors' memoirs scattered in various publications (such as *Annals Mag. N. H.*, *Quart. Journ. Geol. Soc.*, *Geological Magazine*, *Proc. Geol. Assoc.*, *&c.*). Several, however, have not hitherto been adequately illustrated; and, lastly, some are new. Of the species and notable varieties, there are belonging to *Cytherella*, 7; to *Leperditia*, 10; *Beyrichia*, 3; *Beyrichiopsis*, 2; *Kirkbya*, 5; *Ulrichia*, 1; *Bythocypris*, 2; *Macrocypris*, 1; *Argillæciæ*, 1; *Krithe*, 2; *Bairdia*, 8; altogether 42. It is proposed to give a descriptive and bibliographic account of each form, with its range and localities, accompanied by good illustrations. The specimens treated of have come from Donegal, Londonderry, Tyrone, Down, Sligo, Longford, Mayo, and Cork.

PARIS.

Academy of Sciences, May 26.—M. A. Cornu in the chair.—On researches made at the observatory of Madison by G. Comstock, concerning aberration and refraction, by M. Lœwy. The constant of aberration given by these researches is 20″·44.—On the part played by the ring of iron in dynamo-electric machines: reply to the note of M. Potier, by M. Marcel Deprez.—Source and nature of the potential directly utilised in muscular work, from the point of view of the respiratory changes in man after fasting, by M. A. Chauveau. The ratio of carbon dioxide to oxygen, or respiratory quotient, mounts rapidly when muscular work is commenced, falling away, however, if the work is very prolonged. After a rest of one hour the quotient falls to the normal. Fat does not appear to be utilised directly by the muscles, even when the work is done fasting.—The immediate destination of fatty food, by MM. A. Chauveau, Tissot and de Varigny.—On the theory of gases, a letter from M. Boltzmann to M. Bertrand. M. Boltzmann points out that Maxwell himself stated the doubtful nature of his first demonstration. That this one demonstration is false, however, by no means implies that the theorem itself is false, and reference is made to independent proofs by Boltzmann, Lorentz, Kirchhoff, and others.—Reply to the preceding by M. Bertrand. Leaving Maxwell's first demonstration on one side, his second is equally indefensible. While reserving for the present a critical examination of the various proofs advanced, M. Bertrand thinks that, *à priori*, these proofs cannot be real, since all formulæ solving the problems proposed by Maxwell must contain one arbitrary function.—On the vapour pressures of some formic acid solutions, by M. I. M. Raoult. The observations were made by the dynamical method, and give a mean value of 0·713 for the molecular diminution of vapour pressure for formic acid used as a solvent. The ratio of the actual to the theoretical vapour density as found from this number is 1·55, the number obtained by Bineau by direct observation being 1·34.—Description of a mechanical flying machine, by M. Langley (see p. 80).—Letter from M. Graham Bell to M. Langley, on the same subject (see p. 80).—Observations of the sun, made at the observatory of Lyons with the Brunner equatorial during the first quarter of 1896, by M. J. Guillaume.—On the ordinary differential equation of the first order, by M. A. Korkine.—On the conditions of equilibrium of a certain class of systems capable of deformation, by M. B. Mayor.—On a new mode of regulating motors, by M. L. Lecornu.—Remarks on the preceding note, by M. H. Léauté.—On the magnetic torsion of soft iron wire, by M. G. Moreau. An experimental study of the action of a solenoid carrying a current upon a wire under torsion. The increase of torsion observed, called the magnetic torsion, is proportional to the square of the magnetising current, is independent of the diameter of the wire if the latter is small, and is always in the same sense as the original torsion.—Reply to a claim for priority of M. G. Friedel, by M. R. Dongier. The principle utilised was originally due to Fizeau and Foucault.—On the determination of the deviation of the Röntgen rays by a prism, by MM. Hurion and Izarn. The results obtained with an aluminium prism were entirely negative.—On the refraction of the X-rays, by M. Gouy. Using as the source of Röntgen rays the edge of the platinum disc in a Crookes' tube of the "focus" pattern, so that the origin of the rays is practically rectilinear, with prisms of aluminium and of crown-glass, the conclusion is drawn that the index of refraction of the Röntgen rays cannot differ from unity by more than $\frac{1}{200000}$.—Photometry of phosphorescent sulphide of zinc excited by the kathode rays in a Crookes' tube, by MM. C. Henry and G. Seguy. At a fixed pressure the brightness of the zinc sulphide falls off as the experiment is prolonged. There is a certain pressure at which the maximum intensity of light is obtained; a reversal of the current reduces the brightness to about $\frac{1}{17}$ of its original value.—Action of gaseous hydrogen iodide and phosphonium iodide upon thiophosphoryl chloride, by M. A. Besson. The reaction is analogous to that already described for phosphoryl chloride, the products being phosphorus tri-iodide, iodine, hydrogen sulphide, and hydrogen chloride.—On the hydration of pinacoline, by M. Maurice Delacre.—On a new mode of preparation of glyceric acid, by M. P. Cazeneuve. Glycerine is readily oxidised to glyceric acid by silver chlorid in alkaline solution. The acid is extracted by dry acetone, in which glycerine is insoluble.—Action of ethyloxalyl chloride upon aromatic hydrocarbons in presence of aluminium chloride, by M. L. Bouveault. Reaction readily occurs with benzene, toluene, and metaxylene, more difficultly with cymene, with production of the corresponding substituted glyoxylic ethers. With cymene, a new ethyl cymene is obtained as a bye-product.—New derivatives of the cyanoacetic ethers, by M. Guinchant.—Physiological study of the Cyclamens of Persia, by MM. A. Hébert and G. Truffant. The methods of high culture usually followed for these ornamental plants do not necessarily give the largest flowers, a rich soil giving large leaves and small flowers, a poor soil the reverse.—On a new soluble oxidising ferment of vegetable origin, by M. G. Bertrand. The browning of the cut surfaces of certain vegetables, dahlia, apple, and others, is due to the oxidation of the tyrosine under the influence of a soluble ferment, an oxydase. It can be isolated from the roots of the dahlia.—On the buccal and œsophageal pouches of the *Prosobranchia*, by M. A. Amaudrut.—General observations on the distribution of the Algæ in the Bay of Biscay, by M. C.

Sauvageau.—On some Devonian bacteria, by M. B. Renault. Two species of micrococcus are described, found on fossil vegetation of the Devonian age. These are the earliest known bacteria.—On the photography of the retina, by M. Th. Guilloz. —Influence of the liver on the anti-coagulating action of peptone, by MM. E. Gley and V. Pachon.

Berlin.

Meteorological Society, May 5.—Prof. Börnstein, President, in the chair.—Dr. Carl Müller spoke on the adaptation of plants to climate and weather, and discussed the mechanisms by which they take up water and carbon dioxide from the air, as also the various configurations of the earth's surface which either assist, limit or regulate transpiration in dependence upon climate and weather. He further gave a sketch of the means by which radiation is limited during the night, and by which the access of light to the assimilative chlorophyll corpuscles is facilitated and regulated, as also of the multitudinous arrangements for the avoidance of the deleterious action of heavy rain and violent winds.

Physiological Society, May 8.—Prof. du Bois Reymond, President, in the chair.—Dr. Cohnstein discussed certain recent papers dealing with the theory of lymph formation which oppose Heidenhain's view that it is the result of a secretory process, and tend to prove that diffusion and osmosis suffice entirely to explain the passage of the constituents of lymph through the walls of the capillaries.—Prof. I. Munk spoke on muscular work and proteid metabolism, and combated Chauveau's most recent views that the necessary energy is supplied by the oxidation of carbohydrate rather than of proteid material.

Physical Society, May 15.—Prof. du Bois Reymond, President, in the chair.—Prof. Warburg spoke on the action of light on sparking discharge, and demonstrated Hertz's earliest experiments on the influence of ultra-violet rays on the striking distance of the sparks, and on the discharge of negatively electrified bodies. He next showed Hallwach's experiments dealing with spark discharge in light, and finally his own, by which he proved that the action of ultra-violet rays consists in doing away with the retardation which, according to Jaumann's researches, exists at each discharge. This retardation, which is a forerunner of the discharge, and during which some as yet unknown events take place in the path of the spark, is lessened or even completely done away with by the action of light. He conjectured that gases, unlike electrolytes and metals whose conductivity is independent of strength of current, only become conductors when the current has reached a certain intensity. Hence possibly during the retardation the gas is becoming a conductor, and if so the action of light consists in the removal of some obstruction to the establishment of conduction.—Prof. Paalzow gave an obituary notice of the recently deceased member of the Society, Dr. Haensch.

Philadelphia.

Academy of Natural Sciences, May 5.—Dr. F. P. Henry made a communication on *Filaria sanguinis hominis nocturna*, specimens of which had been obtained from the blood of a patient suffering from chyluria due to clogging of the lymphatics by the ova of the parasite. The various forms of the worm, with their life-history, as given by Dr. Patrick Manson, were dwelt on.

May 12.—Dr. Charles S. Dolley described a centrifugal apparatus, which he called a Planktonokrit, for the quantitative determination of the food supply of oysters and other aquatic animals. By means of its use he is enabled to make a large number of plankton estimates in a day, and thus judge of the characters of given areas of water in connection with fish and oyster culture at different times of the day, states of the tide, varying depths, &c. The method employed is that of the centrifuge, an apparatus which consists of a series of geared wheels driven by hand or belt, and so arranged as to cause an upright shaft to revolve up to a speed of 8000 revolutions per minute, corresponding to fifty revolutions per minute of the crank or pulley-wheel. To this upright shaft is fastened an attachment by means of which two funnel-shaped receptacles of one litre capacity each may be secured and made to revolve with the shaft. The main portion of each of these receptacles is constructed of spun copper, tinned. When caused to revolve for one or two minutes the entire contents of suspended matter in the contained water is thrown to the bottom of tubes properly placed, from which the amount may be read off by means of a graduated scale.

CONTENTS.

THURSDAY, JUNE 11, 1896.

ON BEHALF OF SELECTION.

Ueber Germinal-Selection; eine Quelle bestimmt gerichteter Variation. Von August Weismann. Pp. xi + 79. (Jena: Gustav Fischer, 1896.)

THE special purpose of the present treatise, the substance of which was given as an address at the International Congress of Zoologists at Leyden in 1895, is stated by the author to be the rehabilitation of the principle of selection. This principle, though many writers now seek to minimise or to dispense with it, still appears to him to be absolutely necessary for any scientific explanation of the problem of life. The only alternative would be to allow the existence of teleological contrivances, and this in science is inadmissible. The theory of natural selection, says Prof. Weismann, has been rated too highly, and is now suffering the effects of an inevitable reaction. It has not been overrated in the sense of having been credited with too wide a sphere of action, but in the sense that investigators have believed that they understood its whole method of operation, and had a clear conception of all its factors. This, however, is not the case. It has been generally left out of account that besides the individual or personal selection recognised by Darwin, there is a selective process always at work between the various parts of the individual organism (Roux), and even between the ultimate vital units within the germ itself. This conception had already been partly propounded by the author in his Romanes lecture delivered at Oxford in 1894, and in his last rejoinder to Herbert Spencer;[1] it is here stated with greater completeness, and brought into more intimate relation with the doctrine of selection as commonly understood. By its means he claims to have advanced a more satisfactory explanation of the origin of variations and their direction along appropriate lines of development than any as yet proposed.

It is quite impossible to do justice to the view here stated within the limits of a short notice such as this. Those interested in the evolution controversy must be referred to the treatise itself, where they will find the author's position fully explained and illustrated, and from which they will also be able to judge for themselves how far his new conclusions are borne out by the facts and reasoning at his command. The main heads of the argument may, however, be briefly sketched as follows.

The laws of variation provide the stones for the building, which are laid in place by selection. Our knowledge of the selection-value of variations is necessarily limited; we are able, however, to adduce many cases of transformation that can only be accounted for on principles of utility. One such instance is the distribution of colour in butterflies as between upper and under surface, and fore and hind wing. For example, while the upper side of *Protogonius* resembles a *Heliconius*, the under side is like a leaf; this *must* be a consequence of adaptation. So, too, must be the correspondence of the hind wing with the apex of the fore wing on the under surface of many butterflies. In view of the fact that the wing-areas so coloured accord with the usual posture of each species during rest, it is absurd to talk here of simple "correlation." Can mere "laws of development" account for the fact that all leaf-like butterflies are wood-haunting species? The case of *Kallima* by itself is decisive for adaptation.

But how have the suitable variations, which have culminated in such perfect adjustment to needs, originated in the right situations, and in correlation with the appropriate instincts? Herbert Spencer applies Lamarckian principles to the explanation of functional adjustments; but this will not meet the case of such parts as are purely passive in function. The current conception of selection (*i.e. individual* selection) is also inadequate to explain instances of this nature. The root of the process must lie deeper; the variations in question must be *determined in the germ*. This is also shown by the dwindling of disused organs, which disappear in a manner not to be explained by individual selection. Lamarckism (*pace* Lloyd Morgan) will not serve, even as a working hypothesis; and if this be the case, there must be, as Osborn says, a hitherto unrecognised factor in transformation; *i.e.* the direction taken by the variation of a part must be determined by utility. Known facts, as for instance those of artificial selection, will carry us a certain distance towards an explanation. In such a case as that of the long-tailed poultry of Japan, the variation must have been enhanced by selection, and the germ itself must have undergone progressive alteration. For further steps we must have recourse to hypothesis. Variations oscillate about a mean, and selection raises the mean to a higher point. This is satisfactorily accounted for by the theory of "determinants." The determinants are subject to the same conditions of nutrition as body-constituents of a higher degree, and will accordingly differ in size and strength. Hence the opportunity for the progressive raising of the mean by individual selection. But a more important principle is yet to be introduced. The phenomena of retrogression in a disused part show that, as the advocates of Lamarckism have rightly alleged, the simple raising or lowering of the mean by "personal" selection is not adequate to explain the facts. Panmixia will account for the degeneration of such a part up to a certain point, but not for a gradual and continued dwindling ending in complete disappearance.

The really efficient cause is *germinal selection*. This rests on Roux's conception of the "struggle of parts," a principle which must apply to the most minute units of life, not only in the somatic, but also in the germ cells; not, however, of course to "molecules" in the chemical sense. Panmixia starts the determinants of a dwindling organ on the inclined plane, down which they are impelled by intra-germinal selection to their final disappearance. The progressive increase, no less than the decrease of a part, must also be assisted by a like selective process taking place within the germ.

But it is necessary to show how simultaneous useful variations arise under the law of selection. This follows from the fact that the alterations of determinants in the germ, when they are once set going by individual selection, continue without needing the help of that

[1] "Neue Gedanken zur Vererbungsfrage." Jena, 1895. "Heredity once more," *Contemporary Review*, September, 1895.

principle as directed to one definite character alone. Individual selection must, however, step in from time to time, to check the other process when this latter exceeds the demands of utility. This is how so many different modifications can be set going at the same time. It is to be observed that qualitative no less than quantitative modification must be under the influence of the same principle. Selection must affect the "biophors" as much as the "determinants" which they compose. A *quantitative* alteration of constituent biophors appears to us as a *qualitative* modification of the corresponding determinants, and this enables us to understand how "units of variation" may play their part by either simultaneous or independent modification, as on the under side of a butterfly's hind wing. The phenomena of mimicry cannot be accounted for by accidental variations only, but must depend on variation definitely directed by utility. It is to be observed that the determinants and groups of determinants here postulated have nothing to do with Bonnet's preformation theory. The determination of the character of a developing ovum by its own constitution, instead of by the action of external forces, must be admitted by all those who do not, like O. Hertwig, confound the conditions of development with its causes.

The assumption seems inevitable that every heritable and independent variation in the soma depends on the variation of a definite part of the germ; not, as Spencer thinks, on that of *all* the units of the germ. The latter theory leads to needless complication. It is no valid objection to the determinant theory that it deals with invisible elements. The same is true of the chemical assumption of atoms and molecules. The theory justifies itself as such in that it can be used as a formula, to express, for example, the conditions of di- and poly-morphism. The "Hotspurs of biology" forget that all our knowledge is provisional. The assumption of biophors and determinants is parallel to such conceptions as "force," "atoms," and "ether-waves" in the domain of physics.

Epigenesis does not, as has been held, allow a simpler structure for the germ than the counter-theory, and germinal selection explains entirely the direction of variation by utility. It also disposes of the objection that selection cannot cause the variations with which it works. Given the numerical fluctuation of the units, selection will do the rest. Hence both the exactitude and simultaneity of useful variations, a simultaneity which may affect like parts, as in the development of eyes and limbs; or unlike, as in the production of complex mimetic patterns. The principle of selection reaches just so far as utility reaches, and translates, as we have seen, quantitative into qualitative modifications. Utility undoubtedly goes hand in hand with modification, but the dwindling of disused parts shows that the inheritance of characters actively acquired does not cover the whole ground, as the selection theory does; for how can the *disuse* of an organ affect the germ? The Lamarckians are right in pronouncing individual selection inadequate to account for the facts, and also in denying that panmixia could bring about the entire disappearance of a disused organ; they err, however, in attributing the results of Roux's "struggle of parts" to heredity.

Thus then the three stages of selection are (1) personal or individual (that of Darwin and Wallace); (2) histological, as maintained by Roux; and (3) germinal, as pointed out by Weismann. There is indeed another stage, that namely between races or stocks. Here individuals play the same part as organs in individual selection; the analogy, however, is not in all respects complete.

Everything in nature, says the author in conclusion, is purposeful; and this fact can only be accounted for by the theory of selection. What is obscure in the process is so from the imperfection of our methods, not of the principle. All kinds of knowledge ultimately resolve themselves into the hypothetical and unknowable. But doubt is the parent of progress; the veil is raised little by little; and what still remains dark in the explanation points, like the magic wand in the hands of the water-finder, to the hidden springs of truth, ready to yield themselves up to the persevering seeker.

The preface contains a forcible and dignified vindication of the use of hypothesis in scientific investigation; both generally and with special reference to the author's own theory of heredity. Appendices are added, in which several points raised by the paper receive more detailed treatment. The controversies that have centred round Prof. Weismann's former works are not likely to be hushed by the present treatise. We may safely venture to predict that the olive-branch held out to the neo-Lamarckians (p. 59) will not be accepted, though the admissions as to the inadequacy of individual selection will be welcomed by many as evidence of a change of view. The absence of all reference to amphimixis no doubt simplifies the argument greatly; it will, however, be probably used in some quarters to point the moral of the author's inconsistency. But, whatever the amount of acceptance which this latest development of the selection-hypothesis is destined to achieve, there can be no question that the present will rank among the most interesting and suggestive of the Freiburg professor's contributions to biological theory. F. A. DIXEY.

[ADDENDUM.—Since the above notice was written, an English translation of Prof. Weismann's treatise has been issued by the Open Court Publishing Company, Chicago.—F. A. D.]

RIVERSIDE LETTERS.

Riverside Letters; a continuation of "Letters to Marco." By George D. Leslie, R.A., author of "Our River." Pp. xvi + 251. (London: Macmillan and Co., Ltd., 1896.)

ALTHOUGH in his preface Mr. Leslie is careful to state that he cannot assert in the case of these Letters, as he did in the previous volume of his "Letters to Marco," that they were written wholly without view to publication, yet is there little or no change in subject-matter or in style. They are, like the former collection, genuine letters sent to his friend Mr. Marks, R.A., and the topics on which he writes are of mutual interest to the two friends who both, as he says, "love nature for her own sake, untrammelled by the prepossessions that not unfrequently accompany that love among the votaries of science or sport," and in publishing them he doubtless

hopes to find like sympathetic readers among the many who share that love with the two Royal Academicians. Nor do we think he hopes in vain. Admirers of nature are a companionable folk; they love to compare notes, to be asked to share each other's triumphs, to admire each other's finds, and among the topics on which Mr. Leslie dilates are many in which they will find an interest. They will be ready with their tribute of admiration for his *Iris susiana* and his *Cipripedium spectabile* (diverse triumphs), with their sympathetic sorrow at the loss of his old and faithful donkey, and will appreciate his avowal of the inexpressible pleasure he felt at the casual discovery of the exquisitely coloured berry of the lily of the valley. "You will, I dare say, laugh at me for my sentimentality," he writes. We cannot believe that his correspondent did, nor will the appreciative reader. It is the spirit of the true lover of nature, to whom such sights, the more that they come unexpectedly, can ever "bring thoughts that do lie too deep for tears."

Mr. Leslie confesses to a life-long fondness for gardening. He tells us that he had known the Jew's Mallow for more than fifty years before he learnt its botanical name of *Kerria japonica*. We doubt if he is happier for the knowledge. We, for our part, love to think of these old favourite flowers by their nicknames, so to speak, and not by the mongrel Latin names of the florists' catalogues. Among plants, as among men, the possession of a nickname is a sign of popularity, and it is the tender old-world associations that linger round them that give such a charm to some mere list of flowers in the poetry of the Elizabethan age. As regards the name of "Jew's Mallow," which, by the way, belongs to the rather numerous class of plants that cottagers seem to grow better than any one else, Mr. Leslie gives an explanation which is new to us, and which, though doubtless a true one, is far less interesting or suggestive than many a one which our imagination has tried to frame. While on the subject of names, surely Mr. Leslie is wrong in blaming (p. 75) English rose-growers for giving French names to the roses they introduce. In a list of more than 170 kinds we cannot find one case of such unpatriotic conduct, while such well-known instances as Captain Christy, Hon. Edith Gifford, and W. A. Richardson seem to point the other way.

The even tenor of Mr. Leslie's narrative is interrupted by two important events—the great flood of November 1894, and the long frost of the early part of 1895, from both of which visitations he escaped comparatively unscathed. In the case of the latter, he attributes his immunity to having such hardy and well-established plants in his garden; while in the former, the porous subsoil, chiefly gravel and sand, seems to have allowed the water to drain away, leaving only a little mud behind. We wonder, by the way, that Mr. Leslie found no fish stranded after the water subsided. We saw on that occasion hundreds of little ones, chiefly baby roach, left lamenting in a meadow near Marlow. But light as the visitation was, those who feel inclined to envy him the facilities to which he owes his Buck Bean and *Cipripedium spectabile*, will perhaps find some consolation in the sketch of his lawn tennis court on November 19, 1894, which, as he says, "was covered by four feet of water, and formed a lovely calm pool to boat on. I took the opportunity in my boat, of clipping the top of a hedge, which was rather too high to reach under ordinary circumstances." A quaint touch.

Like a true gardener, Mr. Leslie has his gird at the weather, anent the disastrous May frosts of two successive years, and at the devastating efforts of his paid staff, a gardener and a boy, in their attempts to help in the flower garden. In this we cordially sympathise with him. Work among the cabbages and potatoes seems to induce in the former official a breadth of handling quite inconsistent with the delicate stippling (we trust we do not misuse these technical terms) appropriate to the flower garden, while there is no weed, not even couch-grass or bindweed itself, that we would not rather see in our borders than "a boy" with a hoe.

With the many other topics touched upon by Mr. Leslie, we have here no space to deal. The book is pleasantly illustrated with drawings by the author. In the sketch of the Nuthatch, we cannot think that he is represented quite stoutly enough built. We have very frequent opportunities of seeing one at his work, and have been much struck not less with the great development of the muscles of his neck, than with the evident force with which he uses them, which latter is admirably indicated in this drawing.

To conclude, Mr. Leslie's book is not, and does not pretend to be, scientific or exhaustive, but it is eminently readable; and those whose lighter occupations lead them to find interest in the same field as Mr. Leslie, will derive much pleasure from the congenial gossip of "Riverside Letters."

MAN AND NATURE IN FINMARK.

Folk og Natur i Finmarken. By Hans Reusch, Ph.D. Pp. 176. 32 Illustrations. (Kristiania: T. O. Brögger, 1895.)

THE district treated of in this volume is one to which, at the present moment, the eyes of the astronomical world are turned with lively interest; for within its bleak borders the approaching eclipse of the sun will be observed if the atmospheric conditions be favourable. To astronomers, therefore, this book will be specially interesting and opportune; and not to them alone, but to every traveller who has visited the far north of Norway and sought the midnight sun, and even to the still more numerous class who are compelled to content themselves with acquiring a knowledge of lands and peoples solely from books. It is a model of what a book of travel should be; all insignificant details are ignored, but we have the observations and suggestions of one of the shrewdest of observers. Dr. Reusch is deeply interested in the commercial progress and social welfare of his fellow countrymen, and his book is full of valuable suggestions for the advancement of both; while at the same time he is not only just, but very generous in the views he expresses about other races, especially in regard to the Russians, whose territory forms the eastern boundary of Finmark. He describes in graphic and, at times, eloquent language the physical and geological features of the desolate interior of this northern province, which lies far within the Arctic circle, its storm-beaten coasts and its inhospitable, silent, stony deserts, where no tree will

grow, not even a shrub, and from which animal life is almost completely banished. Only in its valleys and its waters is there any abundance of animal life; and consequently its human inhabitants are confined mainly to the valleys and the coast. Finmark has a population of 18,000 Laps and 8000 Fins (the Norsk element is insignificant, being only 1 in 300); but these are actually increasing, the Laps having doubled, and the Fins more than doubled, between 1860 and 1887, in spite of the almost chronic condition of poverty in which they, especially the Laps, live, the frequent hunger from which they suffer, and the dirt which characterises their persons and miserable dwellings. They are, nevertheless, healthy as a whole, though the infant mortality is high; and, in spite of their wretched conditions, they are entirely free from those scourges of civilised life—consumption, cancer, calculus, dropsy and dysentery. The Laps are contented, honest (except as regards reindeer), unambitious, improvident and very drunken; their luxuries being brandy, coffee and tobacco. Imprisonment with bread and water is no hardship to a Lap who has been sent to the house of correction for reindeer stealing; he returns from Trondhjem with the air of a travelled man who has acquired distinction.

In discussing the question of the amelioration of the condition of the Laps, Dr. Reusch writes like a far-seeing statesman. He wishes to see them Norwegianised and civilised by the State, and by the mildest methods; he regards the school as the most effective agent, and recommends free education, free food and lodging for children far distant from their homes, and the compensation of the parents by the State for the loss of the services of the children. He admits that there may be individual cases of oppression on the part of Norwegians, which are never heard of, because the Laps cannot or do not write to the papers like the Danes in Schleswig, or the Germans in the Baltic provinces of Russia. In addition to his own observations, the author has availed himself of all trustworthy local information regarding ethnography, commerce, fisheries, industries, natural history, natural products, and mentions the Pasvig River as the only locality in Europe where diamonds are to be found. He enters very fully into the social condition of all the races in Finmark—Lap, Fin, Norwegian, and the Russian traders. The book is an exceedingly interesting one, and is well illustrated; but it is written in Norsk, a language with which, unfortunately, not many are familiar.

James C. Christie.

OUR BOOK SHELF.

Weitere Ausführungen über den Bau der Cyanophyceen und Bacterien. By Prof. O. Bütschli. (Leipzig: Wilhelm Engelmann, 1896.)

Some five years have elapsed since Prof. Bütschli first published his investigations on the structure of some of the sulphur bacteria: *Chromatium*, *Ophidomonas*, and Beggiatoa, and his views on this subject have been circulated and discussed far and wide. In the above work Prof. Butschli has restated at greater length, and at the same time more precisely, the position which he has been led to assume with regard to this delicate question. We say "delicate question," because at present an opinion one way or another can only be based upon the degree of staining dexterity possessed by the investigator, and the results obtained are directly dependent upon the skill with which such operations are manipulated, whilst their interpretation is also subject to the individual intelligence or originality of the experimenter. Prof. Butschli's own words will best express the object which he has had in view in the publication of the present pamphlet. "Although I have made no fresh investigations in this direction during the years which have elapsed since I first published my views, it has appeared advisable to me for some time past to once more express myself on this question, and to support my opinion by the publication of micro-photographs. . . . I have, therefore, studied afresh during the past winter the greater number of the preparations I made in the years 1889–90, and I can only add that although some preparations have suffered in the interval, I have found everything exactly as I described it in 1890. . . . In the following exposition, which I have put together as briefly as possible, I have principally dealt with the doubts which have been thrown at, and attacks which have been made upon, my former statements." In taking up this essay the reader is, therefore, plunged into a keen scientific controversy, and for those who are concerned one way or the other, the subject-matter is replete with interest, and the scientific *littérateur* will gratefully accept the exhaustive bibliography bearing upon the question; whilst even the layman, who possibly feels but slender interest in the problems surrounding the structural character of these lowly forms of life, cannot but admire the beautiful plates with which the text is illustrated.

A Dictionary of the Names of Minerals, including their History and Etymology. By A. H. Chester. Pp. xv. + 320. (New York: John Wiley and Sons. London: Chapman and Hall, Ltd., 1896.)

The study of mineral names by Prof. Chester was originally begun in the interest of Murray's New English Dictionary: the results of years of patient work and search are conveniently collected together in the volume now issued. In the case of each name a record is given of the name of its author, the year of the first publication, a reference to the work in which the name was announced, the derivation, the reason for the name, and a description of the mineral sufficient to indicate the one to which the name was intended to be applied. For many names the information has been already given in Dana's "Mineralogy"; Prof. Chester has gone to much trouble in the attempt to fill up the gaps which remain, but he gives a long list of names relative to which further information is still required. The book will be useful, not only to those who are interested in nomenclature, but to all who wish to have in a single small volume a brief statement of the chemical composition of the minerals to which names have at any time been given. It may be added that Prof. Chester appends a list of the authors of mineral names with the names for which each author is responsible.

L. F.

Principii della Teoria Matematica de Movimento dei Corpi. Gian Antonio Maggi, Professore ordinario della R. Università di Pisa. Pp. 503. (Milano: Ulrico Hoepli, 1896.)

By omitting illustrations, examples and exercises, and diagrams, the author has managed to give a very compact treatise on all the ordinary formulas of Theoretical Dynamics, including a little Hydrostatics. The author has incorporated into his treatment the most modern ideas of Clifford and Mach; his analytical treatment is elegant and condensed; but a little geometrical and pictorial treatment would give some relief to the procession of equations.

Tidal Migrations of Limpets.

WHILE spending a few days, in March of this year, at the village of Matadona, situated on the south-east coast of British New Guinea, facing the China Straits and nearly opposite to the large island of Rogeia, I had the opportunity of making some observations on the habits of a species of limpets.

On the beach near Matadona there is a sort of rugged platform formed by massive eruptive rocks, extending seawards and presenting in some places a more or less vertical frontage, of some three feet in height, to the sea.

The rocky platform, covered at high tide, is quite exposed at low tide, the sea receding a considerable distance away from it.

Great numbers of limpets live on the sub-vertical front of the rocks, while the numerous small holes and crevices, with which it is riddled, are occupied by Chitons, several of which are often crowded together in a very limited space.

Several species of Patella inhabit these rocks at various points, but as a rule they occur as isolated individuals. One species, however, occurs in large herds of a hundred or so individuals, and it is to this gregarious Patella that the following notes refer.

At low tide these limpets are attached to the seaward face of the rock, quite at its base, adjoining the sand of the beach, and it may then be observed that the zone of limpets, as a general rule, occupies a lower level than that of the Chitons.

It may also be noted that many of the limpet shells are themselves coated with Nullipores and other marine plants.

I have several times observed, at the time of flood-tide, that at the approach of the surf, when the latter gets so close as to spray the rocks, the limpets commence to crawl slowly up the face of the rock, and as the tide rises higher so they climb higher, always keeping above the level of the surf.

It can often be observed that they progress in the form of a triangle, the leader at the apex.

From the time the procession commences until they reach the summit of the rocks, out of the reach of the violence of the surf, the slow movement is practically continuous, the whole company of limpets being found on close inspection to be in motion, and producing a unique effect.

The Chitons, sheltered in their nooks and crannies, undertake no such migration; so that, in general, the zone of limpets is above that of the Chitons at high tide.

When the ebb-tide sets in, the limpets start on their return journey; but I have not actually assisted at the downward procession. Between the tides they are stationary, but they produce no scar on the rocks, so that there can be no question as to their "homing" on the same spot.

On returning to the rocks on one occasion, after a stiff southeasterly breeze, I found the sand banked up to the depth of some two feet against the face of the rocks, approximately up to the level of the zone of Chitons, some of the latter being actually buried beneath the surface of the sand. Others again of the lower lying Chitons had shifted their positions in consequence of the inroad of sand.

None of the limpets were thus buried, and they occupied their usual relative position at the base of the available face of rock. The zones of limpets and Chitons then nearly coincided.

This tidal migration of limpets is interesting in comparison with the periodical phenomena in the lives of other marine organisms; while the elevation of the limpet zone through the formation of a sandbank, may perhaps suggest stratigraphical reflections. ARTHUR WILLEY.

Sydney, April 22.

Butterflies and Hybernation.

IN connection with Mr. Pidgeon's communication, under the above heading, in NATURE of April 2, respecting the probable wintering of a tortoiseshell butterfly in a bath-room, I may state that the hybernation of butterflies is of well-established occurrence in at least certain portions of South Africa, where one species in particular, namely, *Precis sesamus*, Trimen, assembles in numbers at the end of the summer season for the purpose. This very distinct dingy blue and red insect is plentifully distributed in East Griqualand and Natal, especially affecting the road-cuttings between Ixopo and the Ingeli-Zuurberg mountain chain. As remarked in Mr. Roland Trimen's monograph on South African butterflies, it likes shady places under a roadside bank or rocks in a cutting; and Colonel Bowker—an enthusiastic and renowned South African lepidopterist—is quoted as having seen them congregated under rocks and in holes of dry banks, as many as twenty-nine being captured by placing the net over them. Their dark bronzy green under-colouring renders them, when thus massed, almost inconspicuous in association with withered fern, grass, &c., and it is only by startling them that one very often becomes aware of their presence. I particularly call to mind, while on one of my botanical rambles in the Lower Umzimkulu district of East Griqualand in 1885, accompanied by a younger son of Mr. Donald Strachan, unexpectedly flushing at least fifty of these butterflies in the cold frosty season of July, in a secluded glen of the Vubugas rivulet. Upon a little searching among the scrub and bush we discovered a boulder, under which there must have been as many again, if not more. These we roused out with branchlets, some being more torpid than others; but, as we retired from the spot, they all flitted back to their trysting-place. This was at the severest time of the season, and I never doubted, after having observed the massing of this butterfly at all times during the winter, that it emerged safe and strong in the ensuing spring. A description and coloured figure are given in Mr. Trimen's work, vol. i. p. 231, pl. iv. f. 3.

Cape Town, May 20. W. TYSON.

Becquerel's Colour Photographs.

I SEE that the photographs in colour, taken by Becquerel's plan, are said to be mainly due to interference. My own observations do not confirm this statement. A photograph of the spectrum in colours can be readily taken on silver chloride on a glass plate, and be examined both by reflected and transmitted light. The colours in the two cases are identical, which is contrary to the "interference" explanation.

Cannizzaro Memorial.

SINCE my return from Italy, I have been so frequently asked by friends and admirers of Prof. Cannizzaro what form it is proposed to give to this memorial, that I wish, through your valuable medium, to make it known that it is intended to present the Professor with a medal commemorative of the occasion, and to devote the balance of the sums subscribed to the creation of a Cannizzaro prize or medal to perpetuate his memory, the details of which will be left in his hands.

Röntgen Ray Experiments.

IT has been generally noticed that when focus tubes become much blackened, presumably by volatilisation and deposition upon the glass of the platinum of the anode, they cease to be effective owing to the apparent increase in their internal resistance. This is generally attributed to increase in the vacuum due to the occlusion of the residual gas by the platinum black. This may in part be the true explanation, but another is to be found in a curious phenomenon discovered by Prof. Crookes, and described in his 1891 presidential address to the Institution of Electrical Engineers. He says: "It appears that the greater the phosphorescing power of the substance surrounding the poles, so much easier does the induction spark pass. Surround the poles with Bohemian glass or Yttria—two phosphorescent non-conductors of electricity—and the induction spark passes easily: immediately I surround the terminals with a non-phosphorescent conductor" [a film of deposited silver] "the current refuses to pass." Very possibly the deposited platinum in an old or overworked focus tube has a similar effect to the silver in Prof. Crookes' experiment. I have recently had experience with a tube of special form which was much blackened,

and which appeared to have an enormous internal resistance, though its blue appearance and other indications pointed to rather a low vacuum, which seems to show that this is the case.

Dalton's Atomic Theory.

WITH reference to the communications from the authors and from the reviewer of the "New View of the Origin of Dalton's Atomic Theory," published in NATURE for May 14, I beg leave to offer the following remarks. The most serious difficulty which the reviewer advances against the new view, seems to be that Dalton, in his manuscript lecture to the Royal Institution in 1810, states that, as a consequence of an idea respecting elastic fluids which occurred to him in 1805, "it became an object to determine the relative *sizes* and *weights*, together with the relative *number* of atoms in a given volume"; whereas in one of his note-books, under date September 6, 1803, a table of atomic weights is given. The reviewer says:—"The authors notice this conflict of statement, but get rid of it by assuming 1805 to be a clerical error for 1803." In regard to these conflicting dates, I beg to draw attention to a passage which appears to have escaped the vigilance both of the authors and of the reviewer, and which seems to tell strongly in favour of the clerical error theory. In the preface to Part I. of Dalton's "New System of Chemical Philosophy" (1808), the author, writing of himself, says:—"In 1803, he was gradually led to those primary laws, which seem to obtain in regard to heat, and to chemical combinations, and which it is the object of the present work to exhibit and elucidate. A brief outline of them was first publicly given the ensuing winter in a course of lectures on natural philosophy, at the Royal Institution in London, and was left for publication in the journals of the Institution; but he is not informed whether that was done." I do not think there is any room for reasonable doubt that this passage refers, amongst other things, to the same idea as that stated in the manuscript lecture to have occurred to Dalton in 1805. In any case the date 1803 is definitely settled by the sentence referring to the lectures at the Royal Institution, since we know that Dalton's lectures were begun there on December 22, 1803 (compare Roscoe and Harden's "New View, &c.," p. 61). It ought to be possible to place this matter beyond all doubt if the notes stated by Dalton to have been left for publication in the journals of the Royal Institution are forthcoming.

Halley's Chart of Magnetic Declinations.

I AM again able to add another reference to the list of publications of Halley's Chart of Magnetic Declinations (see NATURE, vol. lii. pp. 79, 106, 343).

The chart to which I now refer is one of the plates of Peter van Musschenbroek's work, entitled "Physicae Experimentales et Geometricae de Magnete, Tuborum Capillarium Vitreorumque Speculorum Attractione, Magnitudine Terrae, Coliaerentia Corporum Firmorum"; Lugundi Batavorum, MDCCXXIX. Its size is $19\frac{1}{8}$ inches × $7\frac{3}{4}$ inches, and it takes in the entire circumference of the globe. The title, in the upper left-hand corner, reads: "Tabula Totius Orbis Terrarum Exhibens Declinationes Magneticas, ad Annum 1700. Composita ab Edmundo Halleyo. Simul eum Inclinationibus a Poundio Observatis."

Professional Qualifications.

I AM anxious to prepare myself for the appointment of professor or teacher in chemistry at one of the new technical schools held under the County Councils. Will you kindly inform me the best way to become competent for the post? My age is twenty-five, and I hold first-class certificates in advanced chemistry at South Kensington Science and Art examinations. Is it necessary to obtain the F.I.C. or some similar degree first? Any hints you could give me would be of great help to me.

I must add that at present I have had no experience in teaching.

STUDENT.

LEAP-YEARS AND THEIR OCCASIONAL OMISSION.

AFTER the present year there will be no leap-year, at any rate, in the many countries which now observe the Gregorian style, until 1904; in other words 1900, which would, by the Julian rule, have been a leap-year, will be a common year and have to content itself, like the three years preceding and the three years following it, with the ordinary number of three hundred and sixty-five days. Only once has a similar omission occurred before since the reformation of the calendar in England, viz. in 1800, a year remarkable enough in other respects. The change was originally made in 1582; but as centuries divisible by four hundred without remainder were to be considered leap or bissextile years by either reckoning, there was only occasion, in 1700, when a year was observed as such in England, which was a common year in southern Europe; for 1600 was, as 2000 will be, a leap-year by the Gregorian as well as by the Julian reckoning. Few persons seem to recollect that the change which was effected at Rome in 1582, and followed in this country in 1752, was twofold in its character. If it be desired to make the date in any year correspond exactly with the season of the year, this can of course be done for any future time by inserting or omitting certain intercalary days in the calendar in some such way as is directed by the Gregorian rule to which we are now accustomed, and which was devised by Clavius under the authority of Pope Gregory XIII. But if this had not been done in past ages through want of exact knowledge of the true length of the year, or from any other cause, the fact may either be accepted as inevitable and therefore regretfully disregarded, or we may, if we wish, so change the existing dates in the year from which we start, as to make the seasons correspond with what they were on these dates at some definite period in the past. This is what was actually done, the period selected being A.D. 325, the year of the first great Council of the Church held at Nicæa in the reign of Constantine the Great. At that time the vernal equinox fell on March 21; and as, in consequence of the observance of the Julian length of the year in the interim, it fell in 1582 on the 11th of that month, it was decreed that in the following autumn ten days should be struck out of the calendar, by calling the day after October 4 the 15th, so that in future the vernal equinox (and all the other seasons) should fall as they had done in 325. This arrangement involved another inconvenience besides the awkward enumeration of days in that year, viz. that the seasons were made to disagree appreciably with their dates in the years and centuries immediately preceding the time of the change. However, on the whole, it was thought to be the best arrangement, and it was gradually followed by most of the nations of Europe excepting Russia. In England the change was made in 1752, and the calendar in all respects assimilated to that of the New Style, adopting the Gregorian rules. As in accordance with these, 1700 had not been a leap-year, whereas in England by the Julian reckoning it had been, the two calendars now differed by eleven days; the Act of Parliament therefore, which ordered the change, enacted that the day after September 2, 1752, should be called the 14th.

In speaking of the erroneous length of the year assumed in the Julian calendar, we used the expression "through want of knowledge of the true length of the year, or from any other cause." This was intended as a reference to the fact that, although the exact length of the year was not known in the time of Julius Cæsar, it was certainly known that it fell several minutes short of $365\frac{1}{4}$ days. But it seems that he thought this was sufficiently near for all practical purposes; and a distinguished American astronomer of our own day, in the light of all our modern improved knowledge, is of that

opinion. "The change of calendar," says Prof. Newcomb, "met with much popular opposition, and it may hereafter be conceded that in this instance the common sense of the people was more nearly right than the wisdom of the learned. An additional complication was introduced into the reckoning of time without any other real object than that of making Easter come at the right time. As the end of the century approaches, the question of making 1900 a leap-year as usual, will no doubt be discussed, and it is possible that some concerted action may be taken on the part of leading nations looking to a return to the old mode of reckoning."[1] We are now several years nearer that time than when these words were written, but there is no proposition to return to the Julian reckoning, whilst it seems likely that Russia, which still observes it, will shortly adopt, either at once or by degrees, the Gregorian style, in which case all Christian nations will conform to its use. But it should never be forgotten that Cæsar's main object was to get rid of the previous Roman complication between a solar and a lunar year (endeavouring to keep them together by the insertion from time to time of an intercalary month), and substitute an entirely solar year with only an intercalary day every fourth year, making the length equal to its true amount within a few minutes.

But now comes the question, Is the so-called Gregorian year absolutely exact? Its length is unquestionably nearer that of the true typical year than the Julian year is. But a further modification is necessary if we really desire to make the date of the year correspond with the seasons for all time. The Gregorian rule amounts in fact to considering the year to contain 365·24250 days, whereas the typical year really consists of 365·24220 days, the difference being 0·00030 day, and the Gregorian year is too long by that amount. It in fact drops a leap-year not quite often enough, and a better rule would have been to drop one at the end of each successive period of 128 years. M. Auric has therefore recently suggested in the *Comptes rendus* of the French Academy a modification of the Gregorian rule, which would render it almost absolutely accurate, but which this generation need not, and in fact cannot, decide upon adopting. In 3200 years there are twenty-five periods of 128 years, so that there should be twenty-five omissions of leap-years. But by the Gregorian rule, only twenty-four leap-years are dropped in that interval, or one too few. His proposition then is to make an additional drop or omission of a leap-year in the year 3200 (which would, as the Gregorian rule now stands, be a leap-year), and at every succeeding period of 3200 years, A.D. 6400, 9600, being *not* leap-years. Strictly speaking, however, as the Gregorian calendar was arranged to start from A.D. 325, the first of these periods should expire more than three centuries later than A.D. 3200, and as A.D. 3500 will not be a leap-year by the Gregorian rule of dropping all divisible by 100 without remainder unless also divisible by 400, the nearest way to carry this proposal out practically would be to enact that A.D. 3600 should be an exception and not a leap-year; M. Auric's rule being afterwards applied at intervals of 3200 years, so that A.D. 6800 and A.D. 10000 would not be leap-years, although the Gregorian rule would make them so.

The present writer ventures to propound his own view that this same object would be carried out more straightforwardly by the natural course of dropping a leap-year at the end of each period of 128 years as it was completed, making unnecessary the Gregorian complication of an exception of an exception (*i.e.* the usual leap-year) now proposed to be increased by an exception of an exception of an exception. How exact this one exception would make the calendar (and M. Auric's suggestion would do precisely the same thing in a more roundabout way) may easily be shown. By dropping a leap-year (which usually occurs every fourth year) at the end of 128 years, we obtain in that period ninety-seven common years of 365 days, and thirty-one bissextile years of 366 days, or 46,751 days in all. Dividing this by 128, it is seen that this is equivalent to making each year contain 365·24219 days, the true length of the tropical year being (as above stated) 365·24220 days. It is agreed on all hands that 1900 is not to be a leap-year; and the effect of acting on this proposal would be that the next omission of a leap-year after that date would be in A.D. 2028.

W. T. LYNN.

[1] What Prof. Newcomb means here is making the vernal equinox which the paschal full moon followed, fall on the same date as it did at the time of the Nicæan council.

THE NICARAGUA CANAL.[1]

THE author of this book, though originally an engineer by profession, has become a traveller, a newspaper correspondent in Africa, the Far East, and Central America, and a writer about Eastern countries and problems. The book, accordingly, somewhat naturally reflects the two-fold experiences of the writer. Nicaragua is regarded, on the one hand, as the probable site of a gigantic engineering undertaking for connecting the Atlantic and Pacific, rivalling in commercial importance the Suez Canal; and the feasibility and prospects of the proposed canal are considered from an engineering standpoint, in combination with its commercial and political aspects, which cannot be disassociated from the more purely engineering problems involved. On the other hand, Nicaragua is described, in four chapters in the middle of the book, from the traveller's point of view; and details are given of the manners and customs of the population, the means of communication and resources of the country, with descriptions of the principal towns and other matters of interest noticed in the author's tour through the country. This portion of the book will possess attractions for readers of books of travel; but it appears to have been introduced rather with the object of recording the facts casually collected by the author, than as having any special bearing on the important problem of interoceanic communication. The main object of the book is unquestionably the Nicaragua Canal; and the Suez Canal has demonstrated that it is quite possible to construct a highway for navigation in a country devoid of natural resources, and that the physical conditions of the site selected, and the climate, are the main points which determine the feasibility of isthmian canals.

Several routes have been proposed for forming a water-way across the isthmus of Panama; but the only two which have been deemed capable of practical adoption are the line chosen for the Panama Canal, traversing a narrow portion of the isthmus between Colon and Panama, nearly following the course of the Panama Railway, and the more northerly Nicaragua route crossing a much wider part of the isthmus, in which, however, Lake Nicaragua provides a considerable length of natural water-way. The Paris Commission of 1879, presided over by M. de Lesseps, decided in favour of the Panama route in preference to all the others, including Nicaragua, mainly on the ground that it was essential that an inter-oceanic canal, with prospects of a very large traffic, should be an open water-way unimpeded by locks, like the Suez Canal; and Panama was the only route which could possibly fulfil this condition. When, however, owing to the treacherous nature of the soil under a tropical rainfall, the unhealthiness of the site when the surface vegetation was disturbed by the excavations, and the difficulties experienced in attempting to cope with the floods of the river Chagres, whose course frequently

[1] "The Key of the Pacific, the Nicaragua Canal." By A. R. Colquhoun. Pp. xiii + 443, with numerous illustrations, plans, and maps. (London: Archibald Constable and Co., 1895.)

crosses the line of the canal, it became imperative to introduce locks on the Panama Canal, in order to endeavour to complete the canal within a reasonable time and at a practicable cost, the special advantage of the Panama route disappeared. During the progress of the Panama Canal works, the Nicaragua scheme naturally remained

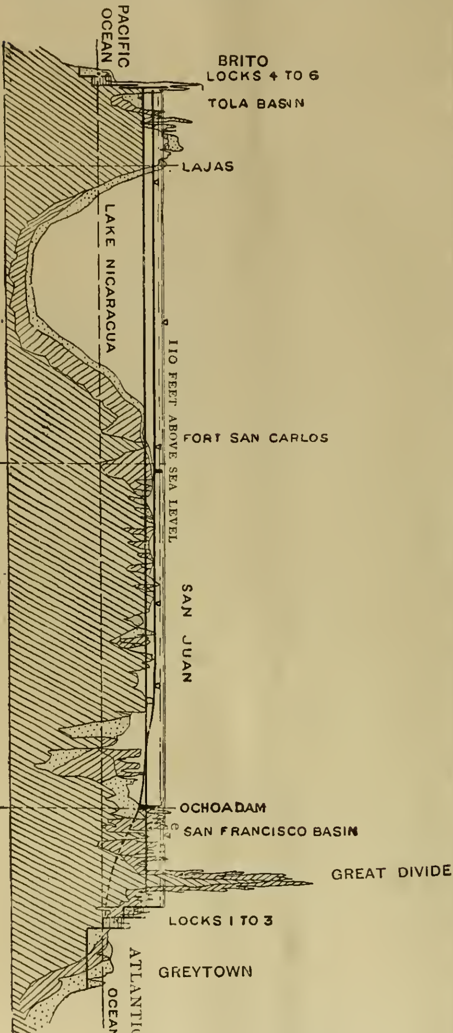

FIG. 1.—Nicaragua Canal (longitudinal section).

in abeyance; but when the works at Panama came to a standstill for want of funds in 1889, and discredit fell upon the promoters, interest was again aroused in the Nicaragua Canal as the only alternative method of connecting the Atlantic and Pacific. The two routes across the isthmus, starting from points 280 miles apart on the Atlantic side, present a remarkable contrast in their natural configuration. The Panama route, starting from Colon in the Bay of Limon on the Atlantic side, and terminating near Panama in the Bay of Panama on the Pacific coast, has a length of $46\frac{1}{3}$ miles; and the ground rises on the Atlantic side with a fairly gentle slope to the central Culebra ridge, reaching a maximum elevation of about 317 feet above sea-level, and descends with a steeper slope to the Pacific. The canal, as originally designed, had to be formed in cutting throughout; and a considerable portion of the excavations had been accomplished along the 27 miles of lower ground at the two ends before the cessation of the works, but comparatively little progress had been made in cutting through the main central ridge, 19 miles in width. The introduction of five locks on each slope has very greatly reduced the amount of excavation for carrying the canal through the central high ground; but it has been estimated that nearly forty million cubic yards of excavation still remain to be effected, and that an expenditure of £36,000,000 is required for the completion of the canal with locks.

The Nicaragua Canal is designed to start from Greytown on the Atlantic side; and after traversing about twelve miles of low marshy land, it is to rise by three locks to its summit-level (Fig. 1). This summit-level is to consist of dammed-up waters of the Deseado, San Francisco, and San Juan rivers on the Atlantic slope, Lake Nicaragua, from which the San Juan River issues, and the Tola basin formed by damming-up the waters of the Tola and Grande rivers on the Pacific slope. The canal is to descend by three locks from the Tola basin to the harbour which is to be constructed at Brito, by two converging breakwaters, at the Pacific end of the canal. The peculiar feature of the Nicaragua Canal is the long summit-level provided, about 110 feet above mean sea-level, by damming-up the rivers on each slope, in addition to the natural water-way across the lake, thereby greatly diminishing the excavation for forming a canal with a total length of $169\frac{1}{2}$ miles between the two oceans, and substituting free navigation along $142\frac{1}{2}$ miles of the route, in place of the restricted navigation of a narrow canal (Fig. 2). In spite, however, of the engineering skill exhibited in adapting the design so as to take advantage of the special physical conditions of the site, two high ridges have to be pierced near the two extremities of the summit-level, known respectively as the Eastern and Western Divides, involving, in the case of the Eastern Divide, a maximum depth of cutting of 328 feet, equalling in depth the Culebra cutting originally contemplated for a tide-level canal at Panama, through strata apparently not very dissimilar to the Culebra cutting, and exposed, as in that case, to an exceptionally heavy tropical rainfall and a very unhealthy climate. In addition to these unusually deep and formidable cuttings, a considerable amount of dredging will be necessary along the upper part of the San Juan River, to procure the requisite depth of 28 feet, together with the removal of rock from its channel at its exit from the lake and across some rapids in its course. The formation of the canal across the low-lying land between Greytown and the locks on the eastern slope, presents no engineering difficulty; but the provision of a deep-water entrance between this portion of the canal and the Atlantic, and its maintenance, constitutes one of the most difficult problems of the undertaking. Greytown, the only place along that part of the coast, for a long distance, where deep water approaches the shore, is situated upon a lagoon which has gradually formed in front of the port, by the advance of the delta of the river San Juan under the influence of the waves raised by south-easterly winds; and it is proposed to carry a breakwater out from the shore into deep water to arrest the littoral drift, under the shelter of which an approach channel is to be dredged. A dam,

composed of a mound of loose rubble stone, is designed to be formed across the San Juan River at Ochoa, below the confluence of the river San Carlos, 44½ miles from the lake, in order to raise the water-level of the river to that of the lake along this distance, amounting to an elevation of 56 feet at the site of the dam; but, considering that it is proposed to place this dam on the unstable sandy bed of the river, and that the floods of the river will pass over its crest, the design has not been given adequate solidity. The dam at La Flor, for the Tola basin on the Pacific coast, is to be given a masonry core; and dams will have to be formed for retaining the water in the San Francisco and Deseado valleys; and upon the security of these dams, and the provision for the discharge of the surplus water of the rivers, will depend the safety of the canal. Mr. Menocal, the engineer of the Nicaragua Canal, estimated the cost of the works originally at £13,000,000; but, after revising the estimates, and making allowance for contingencies, the capital has been fixed at £20,000,000; though on this point Mr. Colquhoun remarks that, "taking into consideration all the circumstances—especially the climate, its debilitating character generally, and the excessive rainfall on the eastern side, the volcanic question, the difficulties as regards labour —I am inclined to think that £30,000,000 in genuine expenditure on the work will be found nearer the mark than the present estimate."

The sites of the two rival schemes for piercing the isthmus of Panama, though differing greatly in their general configuration, are very similar in respect of unhealthiness and excessive rainfall on the Atlantic slope and the nature of the strata to be traversed by the excavations; whilst, though a greater height has been adopted for the summit-level for the Panama Canal with locks, necessitating a larger number of locks than for the Nicaragua Canal, the excavation for the Panama Canal has been reduced considerably below the amount required at Nicaragua, and the maximum depth of the Culebra cutting is now about 150 feet less than that of the cutting through the Eastern Divide. The Panama scheme has a greater length of restricted water-way; but this will be compensated for by the much shorter length of the canal, and by the proposed damming-up of the river Chagres, providing free navigation along one or two of the reaches, as well as controlling its floods. The chief difficulty in the construction of the Panama Canal, as now designed, consists in the control of the discharge of the torrential Chagres, which has, however, been greatly minimised by the introduction of locks; whilst not less difficult problems confront the promoters of the Nicaragua Canal, in ensuring the stability of the dams for raising the water-level, the control of the floods of the rivers impounded to form the water-way, and the formation and maintenance of a deep-water entrance through the advancing sands encumbering the approach to Greytown. Nicaragua, moreover, is much nearer the zone of volcanic disturbances than Panama; and severe shocks from this cause would be fatal to the stability of the dams. The estimated cost of completing the Panama Canal is indeed greater than the highest estimate quoted for the Nicaragua Canal, and more searching investigations of the site are in progress, which may possibly lead to an increase in the estimates; but, on the other hand, the recent very adverse report of the United States Commission on the Nicaragua Canal, both as regards construction and cost, shows that no reliance can be placed on the estimates hitherto presented, and that the designs of the dams and other important works will have to be entirely remodelled. A considerable amount of interesting information about the Nicaragua Canal, and its prospects and probable influence on trade, is given in the first five and two last chapters out of the fourteen contained in the book, the description of the project being naturally largely derived from the reports by Mr. Menocal, the originator of the scheme, often in the very words of the promoter. In comparing, however, the Nicaragua Canal with the Panama Canal, it is evident that Mr. Colquhoun adopts the part of an interested advocate instead of an impartial critic. Thus, after alluding to the main points of the Panama Canal and

FIG. 2.—Nicaragua Canal.

Tehuantepec Ship Railway, he concludes the first chapter with the statement, that—

"The greatest obstacles met with in other localities are: (1) high elevations in the Cordillera separating the two oceans, requiring tunnelling; or (2) a high summit-

level requiring a large number of locks, for which an adequate water-supply is not obtainable; or (3) torrential streams whose control within economical limits defies the skill of the engineer."

"Nicaragua is free from all these obstacles."

It would naturally be supposed that Mr. Colquhoun was summing up the views he had arrived at after due deliberation; but in reality he is only acting as the mouthpiece of Mr. Menocal, for the statement is taken verbatim from this engineer's paper on "The Nicaragua Canal," read before the Water Commerce Congress of Chicago in 1893. Summing up the results of his visit to the Panama Canal, the author says:

"The general impression I gained from my visit was that a large amount of useful work remained accomplished. Still the Chagres river and the Culebra cut appeared to me to be obstacles which may be considered insurmountable"; whereas, in reference to the Nicaragua Canal, he says: "The only serious difficulties are (*a*) the Ochoa dam, (*b*) the Great Divide, (*c*) the Greytown Harbour, none of them, however, insurmountable."

In fact, Mr. Colquhoun exhibits a disposition to minimise the obstacles to the construction of the Nicaragua Canal, and to exaggerate those of the Panama Canal, which occasionally leads him to make contradictory statements in different parts of the book. Thus on p. 116, he says:

"While the lake region and Pacific slope are healthy and superior to Panama, the country embraced between Ochoa and Greytown, in my opinion, presents much the same climatic difficulties. Here occurs the dredging of the channel through the stagnant swamps of the San Juan delta, as well as the cut in the 'Great Divide' and the Deseado and San Francisco basins through dense tropical jungle with a rich (but rotten) surface soil. The past history of the Panama Canal and Panama Railway, with their enormous expenditures of life, makes it imperative to treat very seriously this question, and to take every possible precaution. The climates of both Colon and Panama have greatly improved since the canal days."

Later on, however, in contrasting the two schemes on page 142, he remarks:

"The advantages over Panama are these:—It is a fresh-water canal, with an admirable natural reservoir—the lake; it passes through a region offering prospects of great development, free from the marshy soil, the overpowering heat, and the unhealthy climate of Panama; there is no Chagres River problem, and the 'Divide' stands in a different category to that of the Culebra at Panama."

Again on page 317, he states:

"The Panama isthmus, in addition to being very unhealthy, is a region of floods with very poor local resources; the Suez Canal runs through a sandy desert. Nicaragua stands in marked contrast to both these projects. It has a climate immensely superior to that of Panama, a fertile soil, and internal intercommunication, with great resources both vegetable and mineral."

It may be observed, with regard to these last two extracts, that the Panama Canal with locks would be a fresh-water canal, amply supplied by the Chagres, Obispo, and other rivers; it is curious to call the Suez Canal a project; and the desert traversed by the Suez Canal has proved no bar to its unprecedented financial success.

In justice to English engineers, we must draw attention to a misstatement made by the author on page 138, where he says, with regard to the Suez Canal: "The report of other engineers was equally unfavourable." If Mr. Colquhoun had referred to the report he alludes to, he would have found that the Commission which reported was an international one, that the report was eminently favourable and formed the basis of the subsequent canal works, and that, in addition to the foreign members, three English engineers signed the report.

The Nicaragua Canal has naturally been preferred by the United States, as being nearer, and therefore more convenient for the trade of North America; and we agree with Mr. Colquhoun in considering that the simplest solution of the difficulty of connecting the Atlantic and Pacific Oceans, would be for the Government of the United States to construct the canal, which would be of incalculable benefit to the trade of that country. If, however, the United States is deterred from embarking upon this work by the very unfavourable report of the Government Commission, there appear to be no insuperable obstacles to the completion of the Panama Canal with locks, provided the necessary capital can be raised in France and elsewhere.

IN THE HEART OF A CONTINENT.[1]

THE small size of this record of ten years' travel is in keeping with the character of the author, as revealed in his pages. It is rare to meet a man so simple, brave, and kind-hearted as Captain Younghusband, and rarer still to find a book of travel so straightforward, concise, and modest as this. Many volumes have been written by travellers who have spent fewer months than Captain Younghusband has spent years in Central Asia, and without them it would perhaps have been difficult for us to estimate the magnitude of the difficulties, the overcoming of which the author so quietly relates. But this book differs from those by an entire absence of "padding," of hearsay statements, and of rash speculation. There are chapters indeed which are not purely descriptive, dealing in fact with the opinions formed and the thoughts suggested by ten years largely spent in the most remote and desolate regions of the earth. These thoughts and opinions are perhaps the most striking part of the book, showing in a remarkable manner the power of travel and the contemplation (rather than the study) of nature in educating an appreciative mind. To read the following extract from the five chapters of "Impressions of Travel," one would hardly suspect the author of being a young soldier:—

"No one, indeed, who has been alone with nature in her purest aspects, and seen her in so many different forms, can help pondering over her meanings, and though, in the strain and stress of travel, her deepest messages may not have reached my ear, now, in the after-calm, when I have all the varied scenes as vividly before me as on the day I saw them, and have, moreover, leisure to appreciate them and feel their fullest influence, I can realise something of her grandeur, the mighty scale on which she works, and the infinite beauty of all she does. These impressions, as I stand now at the close of my narrative, with the many scenes which the writing of it has brought back to my mind full before my eyes, crowd upon me, and I long to be able to record them as clearly as I feel them, for the benefit of those who have not had the leisure or the opportunity to visit the jealously-guarded regions of the earth, where nature reveals herself most clearly."

It is rare now-a-days to have the magnitude of the earth, the vastness of distances intervening between places, the month-long silence of desert and mountain forcibly brought before one, and it is startling to reflect how little the resources of modern applied science have done to facilitate journeys in really remote regions. Except for some articles of food and the means of defence, men must travel in Central Asia now just as they travelled in the days of Marco Polo, or even of Alexander.

A sketch of those journeys which have won for Captain Younghusband the gold medal of the Royal Geographical

[1] "The Heart of a Continent." A narrative of travels in Manchuria, across the Gobi Desert through the Himalayas, the Pamirs, and Chitral, 1884-1894. By Captain Frank E. Younghusband, C.I.E. (London: John Murray, 1896.)

Society, will prepare the reader for considering the opinions he was led to form on some important questions regarding men and things. In 1884, at the age of twenty-one, Younghusband was invited by Mr. James to accompany him into Manchuria. Never was invitation more eagerly accepted, and once released of his military duties in India, he threw his whole being into travel. Starting from Newchwang on the Yellow Sea, they pushed northward, visiting the Ever-white Mountain, and describing for the first time the wonderful crater lake on its summit, 8000 feet above the sea, whence flows the river Sungari. Thence the journey continued down the Sungari to Kirin, and north-westward into Mongolia, eastward again, and southward through thriving colonies of strong, self-reliant, diligent Chinamen, to the Russian fort of Nova-Kievsk, south of Vladivostok. Thence they went back to Newchwang and Peking, experiencing all the severity of a Siberian winter, and observing amongst many objects of interest the curious phenomenon of a frozen mist, the particles of ice being so small that the whole air glittered in the sunlight. At Peking, Captain Younghusband was fortunate enough to get permission to return to India overland; and in the spring of 1887 he set out alone with a small party of Chinamen to find his way across the Gobi Desert to Kashgar (Fig. 1), and thence over the Karakoram Mountains into India by a route never previously taken by Europeans. The journey was full of incident, if not of adventure, as far as Hami, 2000 miles from Peking, which was reached in three months, at the end of July. The scenery of the Gobi Desert is powerfully described, and the singular character of the gravel-covered valleys, the cliffs, and the sand-dunes very clearly explained. It is a region of æolian formations where erosion by the alternation of heat and cold and the furious blasts of the prevailing winds has its full course unchecked and unassisted by water or ice. Several instances are recorded of heavy showers of rain, not one drop of which reached the parched ground, so rapidly did evaporation proceed in the hot lower air. Thence the route lay along the edge of the Tian-Shan Mountains to Kashgar, where the glory of the vegetation and the comforts of the Oriental city-life were fully appreciated after the weary crossing of the desert. From Kashgar he proceeded to Yarkand, and thence, with Balti guides, plunged into the sea of mountains with the object of reaching India by a new route. Few enterprises in modern mountaineering have been more daring or more successful than Younghusband's rediscovery and crossing of the Mustagh Pass, inexperienced as he was in the ice-craft of alpine climbers, and solely dependent on native guides, who had themselves never passed that way before. To an experienced and well-equipped alpinist the danger would perhaps be inconsiderable, but the high specialist's point of view is not that from which to judge the work of a traveller, unused to mountains, arriving worn from the desert with no mountaineering outfit.

Fig. 1.—Kashgar.

The next journey recorded is one of remarkable interest, bearing as it does on the political condition of the Indian frontier. It was a reconnaissance of the passes across the great mountain barrier from the north, and a visit to the almost-unknown valley of Hunza in 1889. On this occasion Captain Younghusband was accompanied by a small detachment of Gurkhas, the native Indian troops, whose praises as mountaineers and good companions have been sounded by every European who has had occasion to do difficult work in their company. The description of the primitive little State is so attractive, that the reader feels relieved when he is assured that since its subjection to the Indian Government local autonomy has been maintained, and only the raids of the mountaineers on their lowland neighbours have been checked.

In 1890 commenced a longer and more important journey, which led Captain Younghusband back to Yarkand and Kashgar, where he spent a winter studying the curious cosmopolitan population of the capital of Chinese Turkestan, and doubtless collecting information which, not concerning the general public, is not

referred to in the volume. An interesting contrast is noted between the dreamy philosophical indifference of the Chinese to all questions of geography and natural science, their absolute and voluntary ignorance of other countries, and the quick intelligence of the Turki and Indian merchants who travel far, observe keenly, and hold surprisingly clear views on the difficult political questions which the convergence of the domains of the three dominating powers of Asia brings to a focus in Kashgar. At length Captain Younghusband was ordered back to India, making an exploring expedition through the Pamirs on the way, and it is almost amusing to notice how little he speaks of the sport of that famous region; indeed, the killing of *Ovis poli* seemed to interest him less than the observation of the wolves which weed the herds of the old rams when the weight of years and horns makes their removal a benefit to their species. On the Pamirs there were great political problems in course of development, and such information as the reader gleans of Captain Younghusband's intercourse with Russian officers, only whets his desire for the full history of all that went on. At one time the officers of both nations were drinking the health of their sovereigns, and imparting useful hints as to dealing with exacting natives; the next day the Englishman was informed by his Russian friend that he must quit the Pamirs instantly for Turkestan, and sign an undertaking not to cross into India by any known pass. This was done; but instead of returning to the northern plain, Captain Younghusband set to work to discover an unknown pass, and so fulfilled his mission without breaking his word.

The remaining journeys were of less value as exploration, being carried out in the course of military and political duty in Hunza and Chitral, duty which gave to Captain Younghusband a unique knowledge of the intrepid mountaineers whose misguided rulers precipitated the recent war with the Indian Government. For the details of that war we are referred to the special book in which the author narrates his experience as correspondent of the *Times*.

Captain Younghusband gives in his preface one of the most powerful reasons for the inclusion of natural science in ordinary education. He says: "It has been a ceaseless cause of regret to me that I had never undergone a scientific training before undertaking my journeys. During the last year or two I have done what I can by myself to supply this deficiency; but amongst the Himalaya Mountains, in the desert of Gobi, and amid the forests of Manchuria, how much would I not have given to be able to exchange that smattering of Greek and Latin, which I had drilled into me at school, for a little knowledge of the great forces of nature which I saw at work around me."

With one more quotation we must close this notice. Captain Younghusband has been considering the universality of the law of evolution, and proceeds to apply it to the human species with somewhat remarkable results.

"The traveller," he says, "frequently associates with men who are little more than beasts of burden, and on his return he meets with statesmen, men of science, and men of letters of the first rank in the most civilised countries of the world. He sees every step of the ladder of human progress. And, so far as I have been able to make use of my opportunities of observation, I have not been impressed with any great mental superiority of the most highly-developed races of Europe over lower races with whom I have been brought in contact. In mere brain-power and intellectual capacity there seems no great difference between the civilised European and, say, the rough hill tribesmen of the Himalayas; and, in regard to the Chinaman, I should even say that the advantage lay on his side."

It is to the moral superiority of the European races that Captain Younghusband attributes their power over all the races of the East. The illustrations are comparatively few but good and well-chosen, as the specimen on p. 131 shows, while the maps are sufficient as regards number and scale, and show the routes very clearly.

HUGH ROBERT MILL.

PROFESSOR DAUBRÉE.

ONE of the brightest lights in the geological department of French science has been extinguished by the death of Prof. Daubrée, who has passed away at the ripe old age of eight-two years. Born at Metz on June 25, 1814, he early devoted himself to minerals and rocks, and from the École Polytechnique passed in 1834 into the Corps des Mines. In these early years he paid visits to the mining districts of different parts of Europe, and communicated papers on his observations to the Geological Society of France, the *Annales des Mines*, and the *Comptes rendus* of the Academy of Sciences. He already began to display that breath of view and width of sympathy which distinguished his career, for, while studying minutely the mineral districts of Scandinavia, he devoted much time and thought to the erratic formations then beginning to attract attention, and published his views regarding them. Gradually his attention was more and more directed to the experimental side of his favourite science. He studied the artificial production of various minerals, and entered upon a course of profound investigation in which he became the great leader, and did more than any other observer to advance that department of the science.

With a deep admiration for Sir James Hall, the true founder of experimental research in geological inquiry, he threw himself with especial ardour into the investigation of the influence of water-vapour on minerals and rocks when exposed to high temperatures and under great pressure. The difficult problems of metamorphism had a peculiar fascination for him, and he devoted himself with admirable patience to the task of trying to solve some of them by actual experiment. Every geologist who has studied these questions will feel that by the death of Daubrée, the great pioneer who first lighted up for us some of the darkest pathways of the subject has passed away. The various researches collected in his "Études Synthétiques de Géologie Expérimentale" have taken their place among the classics of modern science.

Nor were his investigations confined to the earth. He took special interest in meteorites, and besides diligently gathering specimens, studied their composition and structure, and carried on a series of experiments in order to reproduce their characters artificially, and thus to throw light on the chemistry of extra-terrestrial space. His last important volumes discussed in ample detail the phenomena of underground water, and traced the various solutions and changes which water is now producing and has formerly effected within the crust of the earth.

M. Daubrée spent the greater part of his scientific life in Paris, where he occupied official posts in the École des Mines and Muséum d'Histoire Naturelle. He retired from office two or three years ago, but continued to interest himself actively in scientific research. He was an indefatigable worker, and, like most busy men, found time for more than his own professional duties. He was one of the most regular attendants of the Académie des Sciences, and one of the most influential members of that distinguished body, serving on many of its Committees, and taking an active part in all its concerns. At its meeting last week, the Academy, after some eulogistic words from the President, at once rose in token of its respect. Daubrée was likewise a member of the Council of the Legion of Honour until the whole body resigned some time ago.

The death of his wife last year was a blow to him, from which he never seemed quite to recover. Yet at the Centenary of the Institute of France, last October, he took his part in the various functions, save those that required evening attendance. He accompanied the excursionists to Chantilly, and was welcomed there by the Duc d'Aumale as an old colleague and personal friend. He began to be somewhat ailing before Easter, and though for a time he appeared to rally, and hopes were entertained that his life might still be prolonged, he died peacefully on May 29, at his house in the Boulevard St. Germain.

A courteous and polished gentleman of the old school, M. Daubrée was everywhere a favourite. There was a certain gentle timidity of manner which gave him a peculiar charm. To those privileged with his friendship he was a warm-hearted kindly benefactor who never spared himself trouble to do a kind act, and to give proofs of the depth of his affectionate nature. A. G.

NOTES.

AT the annual meeting of the Royal Society for the election of Fellows, held on Thursday last, in the Society's rooms in Burlington House, the following gentlemen were elected into the Society:—Lieut.-Colonel Sir George Sydenham Clarke, R.E., Dr. J. Norman Collie, Dr. Arthur Matthew Weld Downing, Dr. Francis Elgar, Prof. Andrew Gray, Dr. George Jennings Hinde, Prof. Henry Alexander Miers, Dr. Frederick Walker Mott, Dr. John Murray, Prof. Karl Pearson, Rev. Thomas Roscoe Rede Stebbing, Prof. Charles Stewart, Mr. William E. Wilson, Mr. Horace Bolingbroke Woodward, and Dr. William Palmer Wynne. The investigations made by each of the new Fellows are set forth in the certificates printed in our issue of May 7.

A DISTINGUISHED philosopher, a wonderful orator, and a mind that was always on the side of advancement in science, art and literature, has been lost to France by the death of M. Jules Simon. He was a great educational reformer, and his voice and pen were always ready to support those things which make for the peace and progress of the world. At the celebration of the Centenary of the Institute of France, last October, he delivered a remarkable discourse, which was printed in full in these columns. His concluding words reflect the broadness of his mind so well, that they may be appropriately repeated now. "Associés et correspondants de l'Institut de France, vous n'emporterez pas seulement d'ici le souvenir des chaleureuses sympathies qui vous ont accueillis. Nous emporterons tous, de cette réunion fraternelle, un redoublement d'amour pour la paix, pour les sciences qui la fécondent et pour les arts qui l'embellissent; et nous travaillerons, chacun dans notre coin préféré de l'atelier universel, à la prospérité de la maison, c'est-à-dire au bonheur de l'humanité." The French Chamber has shown its appreciation of Jules Simon's services in the interests of humanity by voting ten thousand francs for a public funeral, and this has been unanimously agreed to by the Senate.

DR. ROUX has been elected an associate of the Academy of Medicine, in the room of the late M. Pasteur.

SIR GEORGE STOKES and Dr. Carl L. Griesbach, Director of the Geological Survey of India, have been elected honorary members of the Austrian Academy of Sciences.

THE annual conversazione of the Institution of Electrical Engineers will be held in the Galleries of the Royal Institute of Painters in Water Colours, Piccadilly, on the evening of Thursday, June 25.

AN agricultural bacteriological laboratory will shortly be opened at St. Petersburg, under the Ministry of Agriculture and State's Domains. Its chief purpose will be the study of the micro-organisms which are harmful to agriculture, and the pursuit of scientific studies in bacteriology. The laboratory is endowed with a yearly grant of 10,000 roubles (£1000) from the Treasury of the State.

THE members of M. Andrée's balloon expedition to the North Pole left Gothenburg on Sunday, June 7, on board the steamer *Virgo*, bound for Spitzbergen.

OWING to some difficulty in connection with the preparations for his new expedition to Greenland, Lieutenant Peary will be unable to come to England as he intended. The meeting of the Royal Geographical Society on Tuesday, June 16, at which he was to read a paper, will, therefore, not be held.

THE steam yacht *Windward* left St. Katharine's Docks on Tuesday with a very large supply of provisions, a number of sledges, and two additional members for the Franz-Josef Land party of the Jackson-Harmsworth Expedition. It is hoped that she will communicate with the explorers at Cape Flora, Franz-Josef Land, on or about July 20. As soon as the *Windward* has discharged her cargo, she will leave Franz-Josef Land with news of the doings of the explorers, and she may be expected in England by the end of September. About this time next year, if all has gone well, the ship will leave London again to bring the explorers home.

WE regret to record the death of Sir George Johnson, F.R.S., at the age of seventy-eight. He obtained his medical education in King's College Medical School, with which institution his life's work is intimately associated; for at different times he there filled the posts of medical tutor, professor of materia medica and therapeutics, professor of the principles and practice of medicine, and professor of clinical medicine. He was the author of numerous works and papers on medical subjects, the best-remembered of which will probably be those on cholera, epidemic diarrhœa, and Bright's disease. A melancholy interest is attached to the fact that his last work, on "The Pathology of the Contracted Granular Kidney," was published the day before his death. He was elected a Fellow of the University of London in 1862, and was admitted into the Royal Society ten years later.

TOWARDS the end of a long and highly appreciative notice of the life and works of the late Sir J. Russell Reynolds, whose death we briefly recorded last week, the *British Medical Journal* thus refers to the scholarly address which he delivered as president of the successful meeting of the British Medical Association held in 1895:—"His presidential address, as the last important public utterance of a distinguished man, has now a double interest. As we reperuse it we seem to read the departing words of a veteran to whom the sunset of life had already given mystical lore, and whose admonitions to those who shortly will reign in his room have assumed oracular force. At the end of a span of years greater than is usually allotted to men of our calling, he looks with calm survey over a period the most pregnant with scientific progress the world has ever yet known. In a series of terse, closely reasoned passages he points out the vast changes that have occurred in the entire theory and method of physic since he first set foot in a hospital ward, rejoicing in the advances made, warning his successors against the errors and defects that those very advances may beget. Science is great, wisdom is greater; the ampler the armament

of knowledge, the more need to strengthen and train the mind by which it must be carried, the judgment by which it must be exercised; such is the constant moral of Sir Russell Reynolds's final utterance to the medical world. Was it in a spirit of prophecy that he warned the subject-ridden student of to-day of the danger of becoming entangled in the net of an ill-considered and misunderstood technical phraseology, and of juggling with words when he ought to be dealing with concrete things? It was at least the warning of a man, rarer among us as the generations proceed, who had seen both sides of the intellectual shield; who was at once a scholar and a scientific physician."

THE Royal Medals and other awards made by the Royal Geographical Society for the encouragment of geographical science and discovery have, reports the *Geographical Magazine*, been assigned as follows:—The founder's medal, to Sir William Macgregor, for his long-continued services to geography in British New Guinea, in exploring and mapping both the interior and the coast-line, and in giving information on the natives; the patron's medal, to Mr. St. George R. Littledale, for his three important journeys in the Pamirs and Central Asia; the Murchison grant, to Yusuf Sharif Khan Bahadur, Native Indian Surveyor, for his work in Persian Baluchistan and elsewhere; the Gill memorial, to Mr. A. P. Low (of the Canadian Survey), for his five explorations in Labrador; the Back grant, to Mr. J. Burr Tyrrell (of the Canadian Survey), for his two expeditions in the Barren Ground of North-East Canada; and the Cuthbert Peek grant, to Mr. Alfred Sharpe, for his journeys during several years in Central Africa. The following geographers have been elected honorary corresponding members of the Society: M. P. de Semenoff, Vice-President of the Russian Geographical Society; Prof. Dr. Karl von den Steinen, President of the Berlin Geographical Society; Prof. Dr. G. Neumayer, Director of the Naval Observatory, Hamburg; Prof. A. de Lapparent, late President of Council of the Paris Geographical Society; Dr. Albrecht Penck, Professor of Geography in Vienna University; Prof. Dr. Otto Petterson, of Stockholm, the distinguished oceanographer; Prof. Dr. Kan, President of the Dutch Geographical Society; Sr. D. Ernesto do Canto, of São Miguel, Azores, who has edited a series of the Archives of the Azores; Prof. H. Pittier, Director of the National Physico-Geographical Institute of Costa Rica.

THE preliminary announcement of the Local Committee of the American Association for the Advancement of Science for the forty-fifth meeting, being the fourth Buffalo meeting, has just been issued. The meeting of the Association itself will be held August 24-28, and affiliated societies will begin their meetings on August 20, and will continue till September 1. On Monday morning, August 24, the retiring President, Prof. Edward W. Morley, will introduce the President-elect, Prof. Edward D. Cope. On Monday afternoon the several Vice-Presidents will deliver their annual addresses as follows:—Carl Leo Mees, before the section of physics, on "Electrolysis and some outstanding Problems in Molecular Dynamics"; Alice C. Fletcher, before the section of anthropology, on "Emblematic Use of the Tree in the Dakotan Group"; Ben. K. Emerson, before the geological section, on "Geological Myths"; Wm. E. Story, before the section of mathematics and astronomy, on "Intuitive Methods in Mathematics"; William R. Lazenby, before the section of social and economic science, on "Horticulture and Health"; Theodore N. Gill, before the section of zoology, on "Animals as Chronometers for Geology"; Wm. A. Noyes, before the section of chemistry, on "The Achievements of Physical Chemistry"; Nathaniel L. Britton, before the botanical section, on "Botanical Gardens"; Frank O. Marvin, before the section of mechanical science and engineering, on "The Artistic Element in Engineering." Prof. F. W. Putman is Permanent Secretary of the Association, and Eben P. Dorr, of Buffalo, is the Local Secretary for this meeting.

THE Geological Society of America will have a series of excursions before the meeting of the American Association, and will hold a business meeting on Saturday evening, August 22, at which papers will be presented by title, which are to be read and discussed in the geological section in the following week. This is a departure from the custom of previous years, when papers read before this Society detracted from the material presented to the geological section. Prof. Joseph Le Conte is President. Other affiliated societies, which meet two or three days before the General Association, are the American Chemical Society (Dr. Charles B. Dudley, President), Society for the Promotion of Agricultural Science (Prof. Wm. R Lazenby, President), Association of Economic Entomologists (Prof. C. H. Fernald, President), Botanical Society of America (Prof. Charles E. Bessey, President), Society for the Promotion of Engineering Education (Prof. Mansfield Merriman, President). A meeting of the American Mathematical Society will be held after the close of the Association meeting.

FROM a circular recently distributed we learn that Mr. W. Garstang, Fellow of Lincoln College, Oxford, will again conduct a vacation course of study in marine biology at the Plymouth laboratory during the ensuing summer, from July 23 to August 22, inclusive. Students who may desire to join the class should apply to Mr. Garstang before the end of the current month.

IN a contribution to the current number of the *Biologisches Centralblatt*, Dr. Imhof records some observations upon the effects of introducing eels into certain Alpine lakes which seem to him to discredit the generally received opinion that the fresh-water eel spawns only in the sea. The reproduction of the eel is a mystery which has hitherto baffled all attempts at solution; and naturalists may perhaps find some clue to the successful elucidation of the problem in Dr. Imhof's communication. It appears that eels were first introduced into three small Alpine lakes in canton Graubünden in the year 1882. In two of the ponds the fish apparently died; but in the Caumasee they flourished. Extensive additions were made to the stock in the lake in 1887. The eels still thrive well there and attain a length of 1·3 metres. No additions have been made to the stock since 1887, so that all the original eels must be at least eight or nine years old at the present time. Nevertheless, it was discovered last year that young eels were present in the lake: and the knowledge that both sexes are represented there, combined with this discovery, has led Dr. Imhof to the conclusion that the eels introduced into the Caumasee have multiplied in the lake itself. It should be mentioned that the Caumasee is 1000 metres above sea-level, has no apparent outlet, and is fed almost exclusively by subterranean springs. It seems improbable that the presence of the young eels can be due to natural immigration.

AT the recent annual meeting of the Selborne Society, Sir William Flower delivered an interesting address, which is printed in the June number of *Nature Notes*. In the course of his remarks he traced the rise and fall of local museums, and pointed a moral which cannot be too widely known. He said:—"A museum is started or established in some country town, a building is appropriated, various things are brought together, and the people who have done this think they have done a great thing towards cultivating a love for natural history. But in twenty or thirty years when you go again to that place, you will see the building and most of the specimens, but in such a condition that you might well think that the inscription 'Rubbish may be shot here' should be over the doorway. There are a few exceptions here and there, of course, but the

principal reason is that when people start a museum they forget one thing. If you were starting a school the first thing you would think of would be the schoolmaster. A church is of no use without a minister; a garden is of no good without a gardener. None of these things are expected to take care of themselves, yet that is what *is* expected of nearly all the museums in the country. They are set up and the exhibits are arranged, but the last thing anybody seems to think anything about is the curator. A curator is the heart and soul of a museum, and yet we have museums going to decay because nobody thought of the expense that is needful to keep a curator and his staff going. If the thousands, aye, tens of thousands, which have been spent on so-called technical education had only been spent in founding really good local museums—places where any one wishing to know about any bird, or stone, or plant, might go and see for themselves—for I maintain that a museum in its proper sense should be a place of instruction, not merely showing things stuffed and dried like miserable mummies, but giving instruction as to its nature and habit, and any other we might wish to know—what an immense store of useful information would have been gained."

PITHECANTHROPUS is still to the fore. Early this year the Royal Dublin Society published the paper Dr. Dubois read before that Society (*cf.* NATURE, No. 1362, vol. liii., 1895, p. 115), and now he has published a further communication in the *Anatom. Anzeiger* (vol. xii. p. 1), with several illustrations, in which he reiterates his conclusions. A table is given of nineteen anatomists who are classed according to whether they believe Pithecanthropus to be a simian, human, or transitional form; but we imagine that some may object to be tabulated in this form. It is a pity that the ideal reconstruction of the cranium on p. 15, should require to be corrected in two points. Dr. R. Martin has also published a small pamphlet on "further remarks on the Pithecanthropus question," in which he quotes the opinion of a large number of writers on the subject, and particularly lays himself out to attack Virchow; he believes that it is "a low variety of the species *homo*." M. L. Manouvrier concludes in the current number of the *Bull. Soc. d'Anthrop. Paris* (vi. 4e sér. fasc. 6) his erudite "Deuxième étude sur le *Pithecanthropus erectus* comme précurseur présumé de l'homme." This is the most searching scrutiny to which the remains have been subjected, and it forms the most important contribution to the general discussion. It will be remembered that the Javan femur is very human in its characters, the only non-typical differences (putting aside the pathological bony outgrowth) being in the popliteal region. M. Manouvrier has thoroughly discussed this point after having examined several hundred femora, and he finds that the femur of Pithecanthropus fits in a series with normal human femora, and it is not more simian than human; the peculiar variation of the Javan femur is associated with a weak musculature, and the latter may possibly be partly due to the pathological condition already noted; when another femur is discovered, it may be yet more human than this one. In his discussion on the skull, M. Manouvrier gives three alternative ideal restorations and several other comparative diagrams, and he comes to the conclusion that "the Trinil race has arisen from a race of species of very short stature." This is very important from a theoretical point of view; and, with the evidence now to hand, there seem to be grounds for believing that in the evolution of man the femur assumed its human characters in advance of the skull. M. Manouvrier denies that this is a case of microcephaly, and believes that the "missing link" has been found.

REPRODUCTIONS of the decorative artistic efforts of primitive folk are always of great value provided they are perfectly accurately copied. Mr. R. L. Jack, the Government Geologist of Queensland, has recently published a plate or reproductions of aboriginal cave-drawings from the Palmer Gold Field (*Proc. Roy. Soc. Queensland*, xi.), and though we welcome all signs of interest taken in native matters, we cannot but feel some suspicion in the present instance, as there are discrepancies between the figures and the text in certain details. Reproductions of aboriginal drawings lose almost the whole of their value unless the strictest accuracy is preserved. We hope that our colonial scientific societies will publish as many exact transcriptions of native art as they can obtain from travellers, before it is too late.

PROF. R. SEMON, of Jena, whose brilliant investigations on the development of Ceratodus and the Monotremes has already been referred to in these pages, has also turned his attention to the Anthropology of Australia. We cull from our contemporary *Die Natur* (1896, No. 20) the conclusions to which Dr. Semon has arrived respecting the vexed question of the origin of this people. As to culture grade the Australians are ranked above the Veddas, and slightly below the African Pigmies and the Bushmen; the Fuegans are of about the same grade, but the natives of Brazil and the Eskimo are higher. The Australians and Dravidians of India belong to one of the main stems of humanity. The Veddas of Ceylon, judging from the investigations of the Sarasins, belong to a small Pre-Dravidian branch; these arose at a low-culture grade, and have not made any progress since. Other early branches of the primitive Dravido-Australian stem seem to be the curious Ainus of Japan, and the Khmers and Chams of Cambodja. The White Race ("Caucasian") probably came from the Dravidian branch, and thus we Europeans are related to the low savages of Australia; very distantly, it is true, but these are nearer to us than are the Negroes, Malays, or Mongols. It may be noted that these conclusions of Prof. Semon's agree pretty closely with opinions expressed by several English anthropologists.

DR. WESLEY MILLS, Professor of Physiology in McGill University, Montreal, has recently published in the *Transactions* of the Royal Society of Canada (second series, section iv. vol. i. pp. 191-252) a series of papers on the psychic development of young animals. A year earlier, Dr. Mills published the first paper of the series dealing with the psychic development of the dog (St. Bernard and Bridlington terrier). This is now supplemented by observations on the cat, mongrel dog, rabbit, and guinea-pig, and, among birds, the pigeon and the chick. The records are in the form of diaries, from which comparisons and conclusions are then drawn. There is so little systematic record of observations on the instincts and habits of young mammals, that Dr. Wesley Mills' papers are especially welcome. Dr. Mills has also contributed to a discussion on instinct in the correspondence columns of *Science* during the last few weeks, in which Prof. Mark Baldwin also took part. Prof. Baldwin's letters (March 20 and April 10) and Dr. Mills' criticism (May 22) should be read by those interested in the interpretation of the phenomena of instinct in the light of modern theories of heredity.

DURING the last six or seven years, the observation of the pulsations from distant earthquakes has been facilitated by the invention of delicate instruments, such as the horizontal and bifilar pendulums and the long vertical pendulums used in Italy. The investigation of these interesting phenomena suffers, however, from two or three serious disadvantages, which can hardly be removed except by some form of combined action. The instruments employed are of several different types, and they are very unequally scattered over the earth's surface. Many pulsations, again, are recorded which, though of the usual seismic character, cannot be traced to any known earthquake, there

being many countries where no regular organisation exists for the study of these disturbances. We are therefore glad to draw attention to a circular issued by Prof. Gerland, of Strassburg, and signed by nearly all the leading seismologists. Starting from Japan, which possesses the most complete organisation for the study of earthquakes, they suggest a number of stations at which it is desirable that observations should be made. These stations are distributed as uniformly as possible over the earth's surface, and the following places are indicated as especially suitable:—Shanghai, Hongkong, Calcutta, Sydney, Rome, Tacubaya (Mexico), Port Natal, Cape of Good Hope, Santiago (Chili), and Rio de Janeiro. The horizontal pendulum of von Rebeur-Paschwitz is, in the first place, recommended for adoption. As a necessary supplement, it is proposed to form a centre for the collection and publication of reports on the earthquakes of the whole world. These are to be issued as supplements to Gerland's "Beiträge zur Geophysik." They will contain accounts of all earthquakes strong enough to damage well-built houses, and will give in each case the most exact details that can be obtained with reference to the position of the epicentre and the time-records at places adjoining it. Lists are also to be published of all earthquake pulsations registered by the horizontal and other pendulums. The scheme, for which we are chiefly indebted to the late Dr. E. von Rebeur-Paschwitz, can hardly fail to add greatly to our knowledge of earthquakes and their nature, even if it should have to be carried out on a scale less extensive than that now planned.

An interesting series of experiments on the transparency of liquids is described by M. W. Spring in the *Bulletin* of the Royal Academy of Belgium. The first of M. Spring's papers deals with the colours of the alcohols as compared with water. None of the alcohols observed were colourless when the thickness of fluid was 26 metres; methyl alcohol appeared greenish blue, ethyl alcohol the same, but of a less warm colour, and amyl alcohol greenish yellow. The pure blue colour observed in water becomes thus modified by the admixture of more and more yellow as we pass from one term of the homologous series of compounds to the next. The absorbing powers of the various liquids for ordinary light were also observed, and it was found that these formed a descending series, the simplest substance, water, offering the greatest resistance to the passage of light seen by the eye. In a second contribution, the same writer discusses the temperature at which the connection currents begin to produce opacity in a column of water of given length. Where the length is 26 metres the smallest difference of temperature that will suffice is about 0°·57, and is comparable with that which doubtless exists in lakes and seas. The author concludes that we have here an explanation of the varied colours so often seen on water. These result from the differences of temperature caused by sunshine, on the one hand, and by the cooling action of wind blowing on the surface, on the other.

In Nature of June 4, reference was made to a report from Missouri bearing on the question, "Do Röntgen rays exercise any influence on bacteria?" This question forms the title of a paper by Prof. G. Sormani (*Rendiconti del Reale Istituto Lombardo*), in which are described experiments made on sixteen different species of bacteria, both in cultures and when inoculated into living animals. As a result of these experiments, the author has to admit that Röntgen rays do not exercise any sensible action on the cultural and pathogenic properties of the bacteria on which he has experimented.

M. Gaspar Schmitz (*Bulletin de l'Académie Royale de Bélgique*) describes, with diagrams, a fine group of thirty-two upright tree trunks which were discovered in November last on the top of the coal-bearing strata in the Liège basin. There are two theories to account for the existence of these trunks viz. growth on the spot, or transportation from a distance; and from the evidence derived from careful examination of the surroundings, M. Schmitz appears, however, to incline to the latter theory.

The Deutsche Seewarte has issued the tenth yearly series of Daily Synoptic Weather Charts for the North Atlantic Ocean, prepared in conjunction with the Danish Meteorological Institute. The charts are drawn for each morning from December 1, 1890, to November 30, 1891, and embrace a large portion of the adjoining continents of Europe and America. The explanatory text, issued in separate quarterly parts, shows (1) the paths of all barometric minima, or areas of low pressure, with indications of the intensity of the depressions; (2) the positions and the changes of locality of the barometric maxima, or areas of high pressure; (3) the mean position of the isobar of 765 mm. (30·1 inches) for certain definite periods. We have before expressed our opinion that the value of this and similar laborious undertakings for the purpose of investigating the laws which underlie our weather changes, most of which reach us from the Atlantic, can hardly be over-estimated.

The Hydrographic Office of the United States continues the publication and wide distribution of its monthly Pilot Charts for the North Pacific Ocean. These charts contain much information of especial value to seamen, and show the mean average conditions of atmospheric pressure, winds and storms, the positions of areas of high and low barometer, and the principal sailing routes over that ocean. The chart for May last contains the track and log of the American schooner *Aida*, which recently made the passage from Shanghai to Port Townsend, Washington State, in the remarkably short period of twenty-seven days. This passage is an excellent example of what may be accomplished by a captain who takes advantage of existing meteorological conditions and of the information afforded by the Pilot Charts. In the case in point the conditions were certainly favourable, but not exceptionally so.

Limits of space prevent us from reviewing, or even enumerating, the whole of the articles in several bulky volumes recently received; all we can do is to direct attention to their publication. The annual of the Bergen Museum—"Bergen's Museums Aarbog"—for 1894–95 contains numerous papers on physical and natural science, archæology and history, printed in Norsk, German, and French. Among the subjects of the papers are:—Results of cross-fertilisation of fishes, the systematic ennumeration of the marine polyzoa of Norway, the geology of the glacier of Hardanger, the geology and archæology of the plateau of Hardanger, ichthyological notices, foraminifera collected near Bergen during 1894, the decomposition of albuminoids in the human organism, echinoderm fauna in the western fiords, mosses of the Sandefiord region, a certain differential equation, and algæ of the western coast of Norway. The volume also contains reports of the collections and work of the Museum during 1894 and 1895. The "Sitz. der königl. bohmischen Gesellschaft der Wissenschaften at Prague," for 1895, comes to us in two volumes, each filled with papers of scientific value, and many well illustrated. There are altogether fifty-three papers and forty-five plates. Unfortunately for scientific readers having only a limited acquaintance with foreign languages, many of the papers are printed in Chech. Among the subjects dealt with are the Arachnida of Bohemia and Moravia, by Prof. A. Nosek; the chalk formation in the neighbourhood of Ripu, by Prof. V. Zahálka; the palæontology of the older palæozoic formations in Central Bohemia, by Dr. F. Katzer; new descriptions of Tubellaria, by Prof. F. Vejdovski; anemometer observations at Prague, by Dr. J. Frejlach; a contribution to the electromagnetic theory of light, by Prof. F. Koláček; monograph of the fossil flora of Rossitz, Moravia, by

Dr. F. Katzer; some curious geological effects produced by wind-borne sand, by Prof. J. N. Woldřich; the anatomy and development of the brain of vertebrates, by F. K. Studnička; the development of Stylomatophora, by J. F. Babor; determination of the altitude of the celestial pole by means of photography, by Prof. V. Láska; on *Baculus elongatus* (Lubbock) and *Lernæa branchialis*, a contribution to the anatomy of Lernæadæ, by A. Mrázek; studies of isopoda, by B. Němec; on electrolytic superoxide of silver, by Dr. O. Šulc; studies of the Coccidæ, by K. Šulc (this paper is summarised in English); the histology and histogenesis of the spinal cord, by Dr. F. K. Studnička; and new vertebrates from the Permian formation of Bohemia, by Prof. A. Fritsch.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mrs. Bouveri; two Slow Lorises (*Nycticebus tardigradus*), a —— Toad (*Bufo asper*) from Penang, a Roseate Cockatoo (*Cacatua roseicapilla*) from Australia, a Lesser Sulphur-crested Cockatoo (*Cacatua sulphurea*) from Moluccas, two Spinose Land Emys (*Geomyda spinosa*), a Black-spotted Toad (*Bufo melanostictus*) from Singapore, presented by Mr. Stanley S. Flower; two Hairy Armadillos (*Dasypus villosus*) from Uruguay, presented by Messrs. FitzHerbert, Bros.; a Coati (*Nasua rufa*) from South America, presented by Mr. Ernest Brocklehurst; two Herring Gulls (*Larus argentatus*), two Black-headed Gulls (*Larus ridibundus*) British, presented by Baron Ferdinand de Rothschild; a Javan Porcupine (*Hystrix javanica*, white var.) from Java, a Leopard Tortoise (*Testudo pardalis*), a Natal Python (*Python sebæ*, var. *natalensis*) from South Africa, a Cunningham's Skink (*Egernia cunninghami*) from Australia, deposited; a Japanese Deer (*Cervus sika*, ♂), a Red Deer (*Cervus elaphus*, ♀), two Thars (*Capra jemlaica*, ♀ ♀), a Huanaco (*Lama huanacos*, ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OCCULTATION OF JUPITER.—On the evening of June 14 there will be an occultation of Jupiter and his satellites. The planet will disappear at 9h. 52m. G.M.T. at an angle of 113° from the north point towards the east, and reappear at 10h. 43m. at the position angle 293°. The moon will be about three and a half days old, but as it will set at 10h. 56m. the reappearance will occur under unfavourable conditions of observation. The sun will pass below the horizon of Greenwich at 8h. 16m. on the 14th.

COMET SWIFT.—The following elements for comet Swift, 1896, have been derived by F. Bidschof (*Ast. Nach.*, No. 3356).

T = 1896 April 17·68237 (Berlin M.T.)

$$\left.\begin{aligned} \omega &= 1^\circ\ 43'\ 55''\cdot3 \\ \Omega &= 178\ \ 15\ \ 28\cdot1 \\ i &= 55\ \ 33\ \ 42\cdot8 \end{aligned}\right\} 1896\cdot0$$

$$\log q = 9\cdot753076$$

The following is a short ephemeris, the unit of brightness being that on April 19:—

	R.A. h. m. s.	Decl. ° ′	Brightness.
June 11	22 17 17	+72 43	0·05
15	21 52 31	72 21	0·05
19	21 29 5	71 46	0·04
23	21 7 20	70 57	0·03
27	20 47 29	69 57	0·03
July 1	20 29 38	+68 45	0·03

The last published observation is that of Dr. Engelhardt on May 11 (*Ast. Nach.*, No. 3353), when the comet was reported "faint."

SPOTS AND MARKINGS ON JUPITER.—During the past seventeen years Prof. Hough, of the Dearborn Observatory, has made an almost unbroken series of observations of the markings of Jupiter, with the special aim of studying the phenomena by means of micrometrical measures of size and position, rather than by sketches. He considers that for the proper interpretation of the changes taking place, such measurements, extending over a long period of time, are absolutely necessary, while the study of latitude variations is likely to lead to results as important as those of rotation period (*Ast. Nach.*, No. 3354). Photographs have been regarded as capable of giving results as accurate as micrometric measures in the telescope, but long experience has led Prof. Hough to doubt this conclusion. Notwithstanding its varying visibility, the size and shape of the great red spot have changed very little since 1879, though during recent years it was possibly 1″ shorter than when it was most conspicuous. The very slight change in the latitude of the spot during the last seventeen years seems to indicate that this object is the most stable of any of the markings. The average length of the spot, reduced to mean distance, has been 11″·61 or 37°·2. Measures of the equatorial belt and of several spots are also given, and it is worth noting that there are many advantages in Prof. Hough's method of expressing latitudes in direct measures of angular distance. A very suggestive observation was made on February 13, 1895. The third satellite was then observed in transit, at first as a black spot, but afterwards as a white disc; "after emersion, when the distance from the limb of the planet was 0″·4, the outline was sharply defined, and there was an absence of glow around the disc as though the satellite was immersed in a medium which absorbed some of its light."

COMET PERRINE-LAMP (1896 I.), which attracted considerable attention in the early part of the year, has probably now passed out of reach of even the largest telescopes. M. Schulhof has computed hyperbolic elements for this comet; but while the hyperbolic character of the orbit is still uncertain, it is established that the comet is not one of short period.

THE RELATIVE LENGTHS OF POST-GLACIAL TIME IN THE TWO HEMISPHERES.

SOME interesting observations on underground temperature have recently been made at Cremorne, near Port Jackson, in New South Wales.[1] The bore is 2939 feet deep, the mean temperature at the surface is 63° F., and the temperature at the depth of 2733 feet was found to be 97° F. The observations having been made with great care, the resulting gradient of 1° F. per 80 feet would appear to be "a good approximation to the truth." The rocks of the district down to a depth of about 3000 feet consist of sandstones, shales and conglomerates, and therefore, so far as conductivity is concerned, seem to be not unlike the rocks penetrated by the shafts of coal-mines in the north of England, or those in which Forbes' rock-thermometers were sunk in the neighbourhood of Edinburgh.

The estimates of the relative lengths of post-Glacial time in the two hemispheres, given on p. 138, are based on the following assumptions, the first three of which, it is needless to say, are only rough approximations to the truth. It is supposed (1) that in each hemisphere the gradient beneath the ice-sheet at the close of the Glacial period was the same[2]; (2) that the gradient at the surface may now be taken as equal to the average gradient over the whole boring; (3) that when the ice-sheet disappeared, the mean temperature of the district rose *suddenly* to its present value; and (4) that, previously to its disappearance, the temperature of the ground at the base of the ice-sheet was that of the freezing-point of water due to the pressure of the ice above, say 30°·5 F.[3]

The change in the gradient near the surface after a lapse of t years, due to a rise of b degrees in mean surface temperature, is $b/\sqrt{(\pi\kappa t)}$, where κ is the conductivity of rock expressed in terms of its own capacity for heat.[4] Now, the mean temperature over England averages 49°·5 F., so that b is here 19°, and the temperature gradient in the north of England is 1° per 49 feet.[5] Hence,

$$\frac{19}{\sqrt{t}} = \sqrt{(\pi\kappa)}\left(\frac{1}{x} - \frac{1}{49}\right),$$

[1] Report of B. A. Underground Temperature Committee, 1895.

[2] This implies that the Glacial period was of the same—or, if not, of very great—length in each hemisphere.

[3] See a paper "On the Effect of the Glacial Period in changing the Underground Temperature Gradient" (*Geol. Mag.*, vol. ii., 1895, pp. 356-360).

[4] Rev. O. Fisher, *Phil. Mag.*, vol. xxxiv., 1892, p. 339.

[5] Sir J. Prestwich, "Controverted Questions of Geology," p. 203.

where 1° per x feet is the unknown gradient at the end of the Glacial period. At Port Jackson, b is 32°·5, and the gradient 1° per 80 feet. If t' be the corresponding value of t, we have

$$\frac{32 \cdot 5}{\sqrt{t'}} = \sqrt{(\pi\kappa)}\left(\frac{1}{x} - \frac{1}{80}\right),$$

and therefore

$$\frac{32 \cdot 5}{\sqrt{t'}} - \frac{19}{\sqrt{t}} = \sqrt{(\pi\kappa)}\left(\frac{1}{49} - \frac{1}{80}\right).$$

Lord Kelvin, making use of Forbes' observations, finds κ to be 400, so that the last equation reduces to

$$\frac{65}{\sqrt{t'}} - \frac{38}{\sqrt{t}} = 0 \cdot 56.$$

This is satisfied if t and t' are both 2325 years, but so small a length of post-Glacial time is of course inadmissible. But, if t be increased beyond this value by any amount, it may be shown that t' is increased by a smaller amount; that is to say, the length of post-Glacial time must be greater in the north of England than at Port Jackson.

The following table contains some numerical estimates of the relative lengths of post-Glacial time in these districts, calculated from the last equation:—

North of England. Years.	Port Jackson. Years.
10,000	4,800
20,000	6,100
30,000	6,900
40,000	7,500
50,000	7,900
100,000	9,100

Too much stress should not of course be laid on these figures. The second and third, especially, of the assumptions on which they are based, must certainly be far from true. But, at any rate, it seems clear that the ice must have left the neighbourhood of Port Jackson much more recently than it left the north of England.

Whether this conclusion points to an alternation of the Glacial periods in the two hemispheres, and so furnishes an argument in favour of Croll's theory, is perhaps doubtful. But it shows, I think, how important it is, from a geological point of view, that further temperature observations should be made in the coal-mines and other borings of Australia, New Zealand, and South Africa.

C. DAVISON.

PLANT-BREEDING.

WE are most of us now-a-days so much accustomed to see our gardens or our houses bedecked with flowers, and our tables supplied with vegetables and fruit, that we take these things for granted, and do not trouble to inquire whence they come or how they are produced. But if we look back even a few years, we shall see how much larger a share plants have now in our lives than they had then. We shall see, moreover, that while there has been enormous numerical increase, there has also been in many cases continued progression in form and other attributes. We are not concerned here with the introductions from foreign countries, important though they are; our business for the moment lies with the changes resulting from the natural processes of variation as controlled by the art of the gardener. The garden roses of to-day, for instance, are not the roses of a dozen years ago, and as to the sorts that were grown by our fathers and grandfathers, they have, with some few exceptions, utterly gone. It is the same with peas and potatoes, and with most other plants that are grown on a large scale. True, there are some exceptions; there are some "good old sorts," which seem to show by their persistence that they are the fittest to survive under existing conditions. The black Hambro' grape is an illustration, the old double white Camellia is another; but these plants are not reproduced by seed, and therefore do not invalidate the rule, that each succeeding generation of plants differs in some degree from its predecessor. At first the differences are slight, and it may be imperceptible to all but the trained expert; but they become more accentuated as time goes on, till at length they eventuate in forms so different from that from which they sprang, that they would undoubtedly be considered of specific, if not of generic, rank, were not their history known. The Jackman Clematis and its near allies may be cited as cases in point, and still more remarkable are the tuberous Begonias, which, like the Clematis just mentioned, have been created, so to speak, within the last quarter of a century, and which are so different from anything previously known amongst Begonias, that they have actually been raised to the dignity of a genus by M. Fournier, a French botanist. Pansies and Auriculas—garden productions both—are now, morphologically speaking, as good species as are most of the groups of individuals to which this rank is assigned by naturalists. Of their seedlings a large proportion comes true—that is, the parental characteristics are so far reproduced that there is no greater amount of variation among the offspring of many of these artificially-made species than there is in the progeny of natural species. If, as is the case in some Auriculas and the gold-laced Polyanthus, we find little change has occurred during the last few years, may not this relative invariability be the result of the gradual assumption of a degree of stability which we usually associate with the idea of a species? Again, it often happens that these high-bred, close-fertilised plants become sterile, so that their continuance can only be ensured by cuttings, or some means of vegetative propagation. Is not this analogous to the retrogression and ultimate extinction which occur in natural species? It is not necessary here to cite more illustrations; our concern lies rather with the way in which these changes are brought about. This leads us to what is called the improvement of plants, or plant-breeding. There seems to be a growing tendency to make use of the latter term; but if it is to be adopted, it must be taken in a broad sense, and not limited to the results of sexual propagation.

The two methods, made use of by gardeners and plant-raisers for the improvement of plants, are selection and cross-breeding—the latter, as far as results are concerned, only a modification of selection. The natural capacity for variation of the plant furnishes the basis on which the breeder has to work, and this capacity varies greatly in degree in different plants, so that some are much more amenable and pliant than others. The trial-grounds of our great seedsmen furnish object-lessons of this kind on a vast scale. Very large areas are devoted to the cultivation of particular sorts of cabbage, of turnips, of peas, of wheat, or whatever it may be. The object is two-fold—primarily to secure a "pure stock," and secondarily to pick out and to perpetuate any apparently desirable variation that may make itself manifest.

The two processes are antagonistic—on the one hand, every care is taken to "preserve the breed," and to neutralise variation as far as possible, so that the seed may "come true"; on the other hand, when the variation does occur, the observation of the grower marks the change, and he either rejects the plant manifesting it as a "rogue," if the change is undesirable, or takes care of it for further trial, if the variation holds out promise of novelty or improvement. It is remarkable to note how keen the growers are to observe the slightest change in the appearance of the plants, and to eliminate those which do not come up to the required standard, or which are not "true." Where the flowers lend themselves freely to cross-fertilisation by means of insects, as is the case with the species and varieties of Brassica, it is essential, in order to maintain the purity of the offspring, to grow the several varieties at a very wide distance apart. In passing along the rows or "quarters," the plant-breeder not only eliminates the "rogues," and retains what he thinks may be desirable variations, as we have said, but he specially marks those plants which most conspicuously show the characteristic features of the particular variety he desires to increase, and he takes care to obtain seed from the plants so marked. The variety thus becomes "fixed," but it is obvious that that word is only used relatively; really, there is a constant change, which may be either in a retrograde direction, or which may be looked on as an amelioration. Thus, in the seedsmen's advertisements we see announcements of this character: "So-and-so's *Improved* Superlative Cucumber" or whatever it may be. This "improvement," when it exists, is the result of the careful scrutiny, elimination, and selection exercised by the raiser. These are repeated season after season, till a degree of fixity is attained and a good "strain" is produced.

Fierce competition and trade rivalry forbid the growers to relax their efforts, and thus it happens that the pea or the potato of to-day is not the same, even though it may be called by the same name as its predecessors. To the untrained eye, the primordial differences noted are often very slight; even the botanist, unless his attention be specially directed to the matter

fails to see minute differences which are perceptible enough to the raiser or his workmen. Nor must it be thought that these variations, difficult as they are to recognise in the beginning, are unimportant. On the contrary, they are interesting, physiologically, as the potential origin of new species, and very often they are commercially valuable also. These apparently trifling morphological differences are often associated with physiological variations which render some varieties, say of wheat, much better enabled to resist mildew and disease generally than others. Some, again, prove to be better adapted for certain soils or for some climates than others; some are less liable to injury from predatory birds than others, and so on. These co-relations, then, are matters of the greatest importance to the biologist intent upon the study of progressive modification, and to the merchant and the cultivator for practical reasons.

So far we have been alluding to variations in the plant as grown from seed, but similar changes are observable in the ordinary buds, and gardeners are not slow to take advantage of these variations. The buds taken from the base of a plant not unfrequently differ from those which are developed higher up, and these differences are perpetuated by propagation by means of cuttings or grafts. An interesting illustration of the variability in flower-buds is furnished by the gigantic Chrysanthemums which attract so much attention in late autumn. Without entering into technical details, it may be briefly stated that the cultivator selects certain buds, or one bud occupying a special position, and pinches off and rejects most or all the others. The result is not only a flower-head of large size, such as we might expect under the circumstances, but also, in very many cases, one which presents different characteristics to those which are manifested by the other buds when allowed to develop themselves. "As like as two peas in a pod" is, therefore, a motto which has not the significance it had before we had observed that the peas are mostly different, sometimes very much so, and the same thing happens, as has been shown, in the ordinary leaf- and flower-buds; doubtless each cell has its peculiarity, which only awaits a Röntgen ray or some other means to become visible.

Before we leave the subject of buds, some mention may be made of that form of bud-variation which the gardeners speak of as "sporting." Sports are bud-variations which occur suddenly, without assignable cause, and often simultaneously in different regions widely separate. Thus we get peaches and nectarines on the same bough, black and white grapes on the same shoot, or even in the same bunch, finely-cut leaves on a branch that normally produces broad or entire leaves, and so on. The gardener who is on the alert takes care to remove such buds, and to propagate them by cuttings or grafts. If raised from cuttings or layers, the duration of the sport is indefinite; if propagated by grafting, their duration is naturally conditioned by the life of the stock. The problems afforded by sports are of great interest, and are by no means fully solved. Many of them may arise from atavism, or a reversion to an ancestral condition; but of this there is no proof, neither can we appreciate the reason why such reversion should take place. Some may be the result of the dissociation of previously mixed characteristics. Of this we frequently see unmistakable evidence. Thus hybrid berberries frequently show on the same plant an un-mixing or separation of the characters belonging to the two parent-forms.

This brings us to the subject of cross-breeding as a means of obtaining new or improved varieties. Cross-breeding may occur in all degrees from the case where the pollen of one flower is transferred, by insect or other agency, to the stigma of another on the same branch, to that in which the pollen is transferred to the flower on a plant of a different species. Watch a bee travelling over the great disc of a sun-flower, and it will become obvious that (always provided the stigmas be in a receptive condition) cross-fertilisation of neighbouring flowers must take place.

There are endless adaptations which ensure cross-fertilisation, and on the other hand there are very numerous structural arrangements which necessitate close fertilisation, or the fertilisation of a flower's ovules by pollen produced in the same blossom. In view of the copious literature on this matter, it is not necessary here to enter into further detail. It is enough to say that some of the most astonishing results of the gardener's art are due to this practice of repeated cross-fertilisation. When the cross is effected between plants of two different species the term "hybridisation" is made use of, but it is obvious that there is only a difference of degree between the fertilisation of different flowers on the same plant and that of flowers belonging to different species, or even genera.

The tuberous Begonias, before alluded to, are the results of the successive intercrossing or hybridisation of several species, and the result is the production, within little more than a quarter of a century, of a race or garden-group, not to be matched in nature, and so distinct as to have been thought worthy not merely of specific but of generic rank.

Many recognised genera, we might even say most, are not so sharply differentiated as are these Begonias from others of the same family. These extreme crosses apparently are not effected under natural conditions, and some botanists even hesitate to admit the occurrence of hybrids in nature except under very exceptional circumstances. The gardeners and cultivators, however, have long considered certain forms to be of hybrid origin, and one of the most interesting things in this connection of late years is the positive evidence which cultivators have been able to bring forward as to the existence and the parentage of natural hybrids. Certain orchids, now rather numerous, were, from the appearances they presented, assumed to be "natural hybrids" between certain species. That such assumptions were correct has now been proved by the production in our orchid houses of forms indistinguishable from those met with in a wild condition, as the direct consequence of the designed fertilisation of one flower by the pollen of another.

Fairchild, a nurseryman at Hoxton, and the founder of the Flower-sermon, was the first on record to raise a hybrid Pink. Indeed, this is the first artificial hybrid of any kind on record, and it dates from 1719. From that time to this gardeners have gone on selecting, cross-breeding, hybridising. At one time some good folk looked askance at such operations as an interference with the laws of Providence. So much was this the case, that one eminent firm of nurserymen in the early part of the century led their customers to believe that certain heaths (Ericas), which they had for sale, were imported direct from the Cape of Good Hope, instead of having been raised by cross-fertilisation in their own nurseries at Tooting!

Gardeners for the most part pursue their experiments with no scientific aim. The names of Philip Miller, Thomas Andrew Knight, and of Dean Herbert, amongst others, suffice to show that some gardeners appreciate the deep scientific value of these every-day procedures. From the labours of these men and their successors it is made obvious that the cultivator, by availing himself of natural tendencies and natural agencies, and by his power of eliminating conflicting or unpropitious elements, does actually bring about, in a relatively very short period, the same results that occur under natural conditions only after the lapse of a prolonged period. Do not these facts show the desirability for our own biologists to study carefully the results obtained by the gardener, and better still to enter, as their great leader Darwin did, the field themselves as experimenters.

There can be few departments in which greater promise of important results can be held out.

MAXWELL T. MASTERS.

THE ROYAL OBSERVATORY, GREENWICH.

ON Saturday last, the Astronomer Royal presented his annual report to the Board of Visitors of the Royal Observatory, Greenwich. Following the usual custom, a number of astronomers and other men of science were invited to inspect the buildings and instruments of the observatory. The subjoined extracts from the report give a general idea of progress made in some departments since the middle of May last year.

Work with Equatorials.

The new equatorial with photographic telescope of 26 inches, presented by Sir Henry Thompson, is now nearly finished and ready for inspection at Sir Howard Grubb's works. Sir Henry Thompson has completed his valuable gift by the addition of a Cassegrain reflecting telescope of 30 inches aperture, to be carried in place of the counterpoise at the other end of the declination axis.

The 28-inch refractor has been in constant use for micrometric observations during the year, and for spectroscopic observations till November last year.

The measures of the dimensions of Saturn and his rings,

begun last year, were continued on nine nights, and the results communicated to the Royal Astronomical Society in November. The diameters of Jupiter were measured on nineteen nights with the filar micrometer and, for comparison, with the double-image micrometer; the results were communicated to the Royal Astronomical Society in May. The weather during the opposition of Jupiter and Neptune made it impossible for any systematic search to be made for Jupiter's fifth satellite, and the position of Neptune's satellite was only observed on one night.

The Photographic Chart and Catalogue.

With the Astrographic Equatorial 502 plates, with a total of 1224 exposures, have been taken on 123 nights in the year ending May 10, 1895. Of these, 135 have been rejected for various reasons.

The following statement shows the progress made with the photographic mapping of the heavens between May 11, 1895, and May 10, 1896:—

	For the Chart (Exposure 40 m.).	For the Catalogue (Exposures 6 m., 3 m., and 20 s.).
Number of photographs taken	118	353
,, successful plates	89	247
,, fields photographed successfully	79	223
Total number of fields photographed successfully since the commencement of the work	490	732

The question of the utilisation of the photographs taken for the Astrographic Chart, and the formation of a catalogue of stars down to the eleventh magnitude by means of photography, has occupied much attention during the past year, and a satisfactory working scheme for the measurement of the photographic plates and determination of the positions of the stars on them has been brought into operation. It is estimated that if no unforeseen difficulties arise the measures and calculations for the Greenwich Astrographic Catalogue of Stars down to the eleventh magnitude, from Dec. 64° N. to the Pole, will be completed in about seven years, and that the positions of about 120,000 stars will be determined with a degree of accuracy at least twice as great as that of the Astronomische Gesellschaft Catalogues from meridian observations. When it is considered that the Greenwich Astrographic Catalogue will contain about ten times as many stars as the catalogues of the Astronomische Gesellschaft for the corresponding zones, and that the Astrographic Catalogue for the whole heavens will give the positions of from two to three million stars with an accuracy hitherto unattained, and at a relatively small expenditure of labour, the great advantage resulting from the application of photography to the mapping of the heavens will be sufficiently evident.

Spectroscopic and Heliographic Observations.

Since the date of the last report, 189 measures have been made of the displacement of the F line in the spectra of 17 stars, as well as 33 measures of the F line in the spectrum of the moon for comparison.

The spot activity of the sun has steadily declined from the date of the last report. The mean daily spotted area of the sun was decidedly smaller in 1895 than in 1894, but a greater number of small spots was observed.

Magnetic Observations.

The variations of magnetic declination, horizontal force and vertical force, and of earth currents have been registered photographically, and accompanying eye observations of absolute declination, horizontal force and dip, have been made as in former years.

The principal results for the magnetic elements for 1895 are as follows:—

Mean declination	16° 57′·4 West.
Mean horizontal force	3·9739 (in British units). 1·8323 (in Metric units).
Mean dip (3 months, January to March)	67° 15′ 3 (by 9-inch needles). 67° 14′·8 (by 6-inch needles). 67° 16′·6 (by 3-inch needles).
Mean dip (4 months, September to December)	67° 10′ 7 (by 9-inch needles). 67° 11′·8 (by 6-inch needles). 67° 12′·4 (by 3-inch needles).

Uncertainty attaches to the results for mean horizontal force, owing to the permanent effect of the iron in the new Altazimuth Pavilion.

From April to August 1895, during the progress of the building work on the new Altazimuth, the observations of magnetic dip were subject to great uncertainty on account of the masses of iron for the building being stored near the north end of the New Library in immediate proximity to the dip instrument. And after the completion of the building—that is to say, since September 1895—the results of magnetic dip are affected to the extent of about 3′ or 4′ by the permanent iron in the building and instrument. An independent determination at a place sufficiently removed from the Altazimuth building is urgently required. The question, however, has necessarily been deferred, pending the settlement of the site for the new Magnetic Pavilion, which is to be built in Greenwich Park.

The magnetic disturbances during the year 1895 have been comparatively trifling. There were no days of great magnetic disturbance, and sixteen days of lesser disturbance. Tracings of the photographic curves for these days, selected in concert with M. Mascart, will be published in the annual volume as usual. The calculation of diurnal inequalities from five typical quiet days in each month has been continued.

Meteorological Observations.

The mean temperature of the year 1895 was 49°·3, being 0°·1 below the average for the 50 years 1841–1890.

During the twelve months ending April 30, 1896, the highest daily temperature recorded was 87°·3 on September 24. On May 30 a temperature of 86°·2 was recorded. The temperature rose above 80° on 26 days in 1895 as compared with seven days in the preceding year. The monthly mean temperatures were all in excess of the average values with the exception of the month of October, which was in defect. The mean for September was in excess to the amount of 4°·7; that for November in excess by 4°·2, and that for March 1896 by 4°. The mean temperature for the twelve months May 1895 to April 1896 was 51°·1, being 1°·7 above the 50 years' average.

The characteristics of the fine and hot month of September require to be examined in detail. It has been mentioned that the highest temperature of the year (87°·3) occurred on September 24, a temperature greatly exceeding all temperatures previously recorded at this advanced period of the year during the 54 years 1841–1894. Only two instances of higher temperature, both in the earlier part of the month, have been experienced in September, viz. 92°·1 on September 7, 1868, and 87°·7 on September 1, 1886.

The winter of 1895-96 was very mild, and there were only 19 days on which the temperature of the air fell to or below the freezing-point. The lowest winter temperature was 24°·3 on February 25, 1896.

The mean daily horizontal movement of the air in the twelve months ending April 30, 1896, was 275 miles, which is 6 miles below the average for the preceding 28 years. The greatest recorded movement was 1002 miles on December 5, and the least 70 miles on October 20. The greatest recorded pressure of the wind was 27·5 lb. on the square foot on March 16, with an extreme hourly velocity of 49 miles.

The number of hours of bright sunshine recorded during the twelve months ending April 30, 1896, by the Campbell-Stokes instrument was 1176 out of the 4465 hours during which the sun was above the horizon, so that the mean proportion of sunshine for the year was 0·263, constant sunshine being represented by 1. In the corresponding period for 1894–95 the number of hours of sunshine was 928, and the mean proportion 0·208.

The rainfall for the year ending April 30, 1896, was 19·76 inches, being 4·78 below the 50 years' average. This is the smallest rainfall since the year 1884–85, when the fall was 19·61 inches. In 1864-65 the rainfall was 17·71 inches, and in 1858–59 it was 17·38 inches. The number of rainy days in the twelve months was 151.

Re-organisation of the Staff.

The scheme for the re-organisation of the staff, referred to in last two reports, has now been sanctioned. With a view to strengthening the supervising power and increasing the permanent subordinate staff, an additional chief assistant is appointed, and the five second-class assistants of the old staff are to be replaced by eight established computers, two of these to be of a higher grade, the number of temporary computers being correspondingly reduced. The future staff will be thus constituted:—

Upper staff, two chief assistants and five assistants; lower staff, two higher grade established computers and six established computers; temporary staff, non-established computers.

Mr. P. H. Cowell was appointed the additional chief assistant on April 20, and it is hoped that the appointments of the established computers will very shortly be made. Mr. Criswick has retired on pension after a useful and honourable service of forty-one years at the Observatory, and Mr. Hollis has been promoted to fill the vacancy thus occasioned in the staff of first class assistants.

THE ROYAL SOCIETY OF CANADA.

THE annual meeting of the Royal Society of Canada was held at Ottawa on May 18, and the three following days. In addition to the papers read before the literary sections of the Society, a large number of important papers were presented in the two Science Sections.

In Section III. (Mathematical, Physical and Chemical Sciences), Profs. Cox and Callendar presented the results of recent investigations carried on by them in the physical laboratories of McGill University, in which they have succeeded in demonstrating that Röntgen rays are not unaffected by magnetic attraction, as Röntgen states, but on the contrary are affected in a marked manner when tested experimentally under favourable conditions, the approach of the magnet causing a marked deviation of the kathode rays within the tube in one direction, and at the same time a corresponding deviation of the Röntgen rays without the tube in the opposite direction. These observations are of especial importance as bearing on the question of the relation of Röntgen rays to the kathode-rays, Rontgen having considered the former as differing from the latter in that they were not influenced by magnetism.

In the same Section, papers were also read by Messrs. Alex. R. Mellanby and John T. Farmer, Royal Commissioners' Scholars, on investigations carried out in the laboratories of McGill University; the former, "on an investigation as to the thermal and plant efficiencies of compound, triple and quadruple expansion engines," and the latter, "on the efficiency of $\frac{1}{2}$-inch jets from circular orifices, impinging upon surfaces of different forms."—Prof. Bovey communicated the results of a series of experiments on the strengths of the woods of the hemlock, red pine, and white pine.—Mr. Howard Barnes presented the results of a series of very accurate measurements of the temperature of the waters of the St. Lawrence, opposite Montreal, during the coldest part of last winter. It was shown that the greatest variation in temperature did not exceed $\frac{1}{100}$ of a degree Centigrade. The measurements were carried out with a view to ascertaining whether the formation of frazil ice was accompanied by any considerable changes in temperature, such as have been described by some observers. It was found that as the river does not vary throughout its depth by so much as one-hundredth of a degreee from the freezing point, the formation of frazil does not depend on any considerable lowering of the temperature of the water. The formation of fine needles of ice all through the water of the river is probably aided by fine particles of sand and other suspended material acting as nuclei, since earthy matter is found embedded in the frazil attached to the under side of the surface ice.

In Section IV. (Geological and Biological Sciences), Sir William Dawson read a paper on fossil sponges and other organic remains from the rocks of the Quebec Group at Little Metis.—Prof. D. P. Penhallow read a paper which embodied his final deductions on the generic characters of the North American Coniferæ as exemplified in the microscopic structure of the woods.—Prof. Ramsay Wright gave the results of his studies of a great number of minute forms of life obtained from certain of the Canadian fresh-water lakes by means of a very fine tow-net, among which he describes a number of new species, and compares others with closely allied forms already recognised in the lakes of Scandinavia and other parts of Europe. He also communicated a paper by Mr. E. C. Jeffery, on the morphological nature of the medullate stellar structures of certain plants.—Dr. George M. Dawson, in a communication on secular climatic changes in British Columbia, showed from a study of the rainfall of the Province, as evidenced by the varying height of lakes without outlet, that the last few years have been more humid than any preceding them in a period of about fifty years.

Other papers were read by Prof. Edward E. Prince, Dr. A. R. C. Selwyn, Dr. William Saunders, and others.

The usual public lecture was delivered by Prof. Prince, Dominion Commissioner of Fisheries, on the fishery industries and resources of Canada.

The Society decided to petition the Dominion Government to establish a marine biological station at some point on the Atlantic Coast of Canada, as soon as possible, as recommended in a recent report of the Dominion Commissioner of Fisheries.

Prof. Ruttan and Prof. Adams, of McGill University, and Mr. W. Bell Dawson, of the Hydrographic Service, were elected Fellows of the Society, to fill three vacancies recently caused by death.

The meeting was well attended, and was successful in all respects. At the conclusion of the meeting the Fellows of the Society were entertained at a garden party, by their Excellencies the Earl and Countess of Aberdeen, at Rideau Hall.

THE CIRCULATION OF ORGANIC MATTER.

AT the evening meeting of the Royal Institution on Friday, April 24, Dr. G. V. Poore gave a discourse on the circulation of organic matter. Without attempting to define "organic matter," Dr. Poore began by saying that all organic matter was combustible, and that all our combustibles were of organic origin. A comparison was made between combustion in a furnace and the combustion of food in the body of an animal, and it was shown that whereas in the furnace the fuel was used up and furnace wore out, in the animal there was increase of size, while its droppings stimulate the soil to an increased production of food. This apparent increase was probably due to the holding in suspension by the extra growth of plants of both water and soluble salts, which otherwise would percolate the soil and find their way to the sea. Recent experiments made it certain, also, that some of the atmospheric nitrogen was appropriated by microbes in the soil. The animal was a true regenerative furnace, and led to the increase of the herbage at the expense of the sea on the one hand, and the atmosphere on the other. It was impossible to imagine an increase in one direction without some compensating decrease in another direction. When organic matter collected under water, fermentations were set up, and the organic matter was reduced instead of being oxidised. The tendency of organic matter, when thus treated, to form combustible bodies was very remarkable. The inflammable gases which sometimes formed in cesspools, and the marsh gas evolved by mud in ponds and rivers, were familiar examples, as were also the alcohols formed by the fermentation of carbohydrates. Our immense stores of coal and peat were due to the silting up of marsh plants in past ages and in recent times, and so-called mineral oils were certainly of organic origin, as were also the nitrates which were so much used in the manufacture of explosives. If we were to judge what *has been* by what *is*, it was impossible not to come to the conclusion that life must have preceded combustion in this world. This biological theory of the cosmogony made the world subject, like all other things, to the processes of development, evolution and decay, and he believed that such a theory had fewer drawbacks than might at first sight appear.

Organic matter was our capital in this world, and the more frequently we could make it circulate the greater would be our increase of material wealth. If we burnt it or threw it into the sea, we thereby spent money for dissipating our capital; but if we placed it on the land, we increased our capital and earned frequent dividends. The *rôle* of microbes in the soil, in bringing about the humification and nitrification of organic matter, was next dealt with. It was shown that farming without frequent additions of organic matter to the soil, must end in ultimate failure. We found everywhere that vegetable organisms co-operated with animals in the destruction and circulation of organic matter, and it appeared to be probable that the correlation of the biological forces was not less rigid than the correlation of the physical forces.

Allusion was made to the observations of M. Megnin on the destruction of animal bodies by successive squadrons of insects and microbes, and many facts were brought forward to show that the comparatively new doctrine of symbiosis was probably of universal application. The intestines of every animal swarmed with microbes which were essential for digestion, during life, and at death were active in starting the dead body upon the cycle of events which led to its ultimate circulation and re-

appearance in plant form. There were no less than 628 species of fungi which flourished in excrement, and of these no less than 402 were peculiar to certain animals. There could be no doubt the excrement often contained the organisms which led to its dissolution and circulation.

The proper course to pursue with organic matter was to place it near to the surface of well-tilled ground, and such a course seemed to be both profitable and safe. By mixing it with water we had all the evils of putrefaction, while our capital was thrown into the sea, and our water-supplies were poisoned by leakage. Our methods of sanitation inevitably lead to overcrowding, and farmers were often taxed to provide expensive apparatus, which merely deprived them of organic matter which otherwise might fertilise the land instead of involving them in a ruinous expense.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Some friends of the late Prof. Sir T. F. Wade have offered to the University, by way of memorial, a sum of £100 for the construction of a catalogue of the Chinese books in the University Library. These books were his own gift, and during his lifetime he held the post of Honorary Curator of the collection.

Mr. J. E. Gray, and Mr. S. D. Scott, of King's College, have been appointed to work at the University's table in the Zoological Station of Naples and Plymouth respectively.

Sir Walter Gilbey has offered to the University a fund sufficient to provide an income of £25 a year for twenty-one years as an endowment for a Lecturer in the History and Economics of Agriculture. The Council of the Senate recommend that the benefaction should be gratefully accepted, and propose suitable regulations for the foundation of a "Gilbey Lectureship."

The Library Syndicate propose that the new class of "Advanced Students" should have the same privileges as Bachelors of Arts in respect of borrowing books from the Library.

The discussion by the Senate of the proposal to expend £27,000 in acquiring sites adjoining the congested area occupied by the New Museums was unusually full and detailed. The price is generally held to be high, but the importance of the ground in question for the extension of the scientific and other departments was strongly urged. The question is to be decided by a vote to-day.

In the Mathematical Tripos, Part I., all but one of the candidates have obtained honours. Fourteen women are among the successful. The class list will be published on June 16.

The Deputy-Professor of Pathology, Dr. A. A. Kanthack, announces four courses of instruction in different branches of his subject, including bacteriology, during the ensuing Long Vacation (July and August).

Honorary degrees are to be conferred on June 18 on a number of foreign men of letters, and upon Prof. Carl Gegenbaur, of Heidelberg, Prof. Felix Klein, of Göttingen, and Prof. Simon Newcomb, of Johns Hopkins University, Baltimore.

Mr. Charles Smith, Master of Sidney Sussex College, has been re-elected Vice-Chancellor.

"THE College of New Jersey," universally known as "Princeton," has just changed its corporate name to Princeton University. An attempt will be made to raise 2,000,000 dols. in connection with its approaching sesqui-centennial celebration this fall. John I. Blair has contributed 150,000 dols. for a dormitory to be known as Blair's Hall, and another friend has contributed 100,000 dols.

THE Council of Firth College and the Committees of the Medical School and Technical School, Sheffield, have each passed resolutions in favour of a joint application for a charter of incorporation with the Victoria University, Manchester. A meeting of representatives from these educational establishments has been held, at which the form of the proposed charter was finally agreed upon, and a small Committee appointed to bring it before the proper authorities.

A RESOLUTION was moved at the last meeting of the Technical Instruction Committee of the Glamorganshire County Council to the effect that funds should be allocated to the establishment of five musical scholarships, each of the value of £40 per annum, tenable at the University College, Cardiff. The resolution was not seconded. It was decided to defer the matter until the next meeting. The two issues which are here raised, (1) whether the funds for technical instruction can rightly be devoted to musical education, and (2) whether it is desirable to encourage such instruction at a University College, certainly require some time for consideration.

SCIENTIFIC SERIALS.

The Quarterly Journal of Microscopical Science for May 1896 (vol. xxxix. part 1) contains:—On the blood of Magelona, by Dr. W. Blaxland Benham (pl. 1). The blood of *Magelona papillicornis* is totally different in structure from that of any other known Chætopod, in that it consists mainly of very small madder rose-coloured, non-nucleated globules, embedded (rather than floating) in a very small amount of colourless plasma; amongst the corpuscles occur isolated nuclei. It was originally demonstrated by Lankester that nuclei occur in the red fluid of the common earthworm, and this observation has been extended to sundry other Annelids by various observers. In these cases, as in Megalona, the nucleus is surrounded by very little, if any, protoplasm, and floats freely in the perfectly liquid plasma, which is coloured red by hæmoglobin, or in a few cases green by chlorocruorin or chlorochromin; while in some Oligochætes the plasma is colourless. The so-called "corpuscles" or coloured globules of Magelona differ from those observed in other Annelids, not only in position, viz. within blood-vessels instead of in the cœlom, but also in structure and in their behaviour to chemicals. These globules "stand, as it were, midway between the coloured liquid plasma of Annelids generally and the coloured corpuscles of mammalian blood." The colouring matter showed no absorption bands, when spectroscopically analysed.—Fission in Nemertines, by Dr. W. Blaxland Benham (pls. 2 and 3). The fact that many Nemertines break up into pieces when irritated is well known, but the phenomenon has received but little attention, nor does it seem to have been definitely ascertained whether it is a normal occurrence. From these researches it seems, however, proved that these pieces are gonads, thrown off from the male and female worms, about the time the sexual elements are mature. The species examined belonged to the genus Carinella, and was probably *C. linearis*, Montagu.—Studies on the nervous system of Crustacea, by Edgar J. Allen (pl. 4). IV. Further observations on the nerve elements of the embryonic lobster.—Notes on Oligochætes, with the description of a new species, by Edwin S. Goodrich (pls. 5 and 6). The author first describes a new species of Enchytræus, found in a garden at Weymouth, also near Oxford and London (*E. hortensis*); it is, when full grown, about 15 mm. in length, and milky white in colour, the anterior end being sometimes yellowish. The chetæ are in bundles of from three to four, generally three in the dorsal and four in the ventral bundle; they have a straight shaft and a hooked inner end; a small dorsal head-pore is found between the pro-stomium and the first segment. In a favourable light the cuticle is seen to be covered throughout with fine hair-like processes, similar to those described by the author in *Vermiculus pilosus*. Three kinds of cœlomic corpuscles are described as very characteristic of this worm: (*a*) amœboid; (*b*) oval corpuscles of the type so frequently met with in the Enchytræidæ, nearly twice as large as the amœboid, flattened oval in form, and filled with refringent granules; and (*c*) a third type of a discoid form, but the refringent granules, when they escape by rupture of the corpuscle wall, form a long thread of transparent homogeneous substance, closely coiled. These threads are possibly of an albuminoid nature.—On the development of *Lichenopora verrucaria*, Fabr., by Sidney F. Harmer (pls. 7–10). The author in a previous volume of this journal, from a study of Crisia, had suggested that embryonic fission would be found to be characteristic of the whole group of cyclostomatous Polyzoa. A chance discovery of large numbers of the colonies of *Lichenopora verrucaria*, Fabr., in all stages of development, has enabled him not only to show that this fission occurs here in an equally marked manner as in Crisia, but to discover some previously unsuspected phenomena in the life-history of *Lichenopora verrucaria*. Among these is the restriction of the production of an embryo to one or two of the oldest Zoœcia in the normal development.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 21.—"Helium and Argon. Part III. Experiments which show the Inactivity of these Elements." By Prof. William Ramsay, F.R.S., and Dr. J. Norman Collie.

To chronicle a list of failures is not an agreeable task; and yet it is sometimes necessary, in order that the record of the behaviour of newly-discovered substances may be a complete one. It is with this object that we place on record an account of a number of experiments made to test the possibility of forming compounds of helium and argon.

It will be remembered that in their memoir on Argon (*Phil. Trans.*, vol. clxxxvi., A), Lord Rayleigh and Prof. Ramsay described numerous experiments, made in the hope of inducing argon to combine, all of which yielded negative results. Two further experiments have been since made—again without success.

(1) The electric arc was maintained for several hours in an atmosphere of argon. A slow expansion took place. The resulting gas was treated with caustic soda and with a solution of ammoniacal cuprous chloride, and, on transference to a vacuum-tube, it showed the spectrum of argon along with a spectrum resembling that of hydrocarbons. Having to leave off work at this stage, a short note was sent to the *Chemical News* on "A Possible Compound of Argon." On resuming work after the holidays, the gas was again investigated, and, on sparking with oxygen, carbon dioxide was produced. But it was thought right again to treat the gas with cuprous chloride in presence of ammonia, and it now appeared that when left for a sufficient time in contact with a strong solution, considerable contraction took place, carbonic oxide being removed. There can, therefore, be no doubt that, although apparently all gas had been removed from the carbon electrodes before admitting argon, some carbon dioxide must have been still occluded, probably in the upper part of the electrodes, and that the prolonged heating due to the arc had expelled this gas and converted it into monoxide. It appears, therefore, certain that argon and carbon do not combine, even at the high temperature of the arc, where any product would have a chance of escaping decomposition by removing itself from the source of heat. It is hardly necessary to point out that such a process lends itself to the formation of endothermic compounds such as acetylene, and it was to be supposed that if argon is capable of combination at all, the resulting compound must be produced by an endothermic reaction.

(2) A product rich in barium cyanide was made by the action of producer gas on a mixture of barium carbonate and carbon at the intense temperature of the arc. This product was treated by Dumas' process so as to recover all nitrogen; and, as argon might also have entered into combination, the nitrogen was absorbed by sparking. All the nitrogen entered into combination with oxygen and soda, leaving no residue. Hence it may be concluded that no argon enters into combination.

(3) A mixture of argon with the vapour of carbon tetrachloride was exposed for several hours to a silent discharge from a very powerful induction coil. The apparatus was connected with a gauge which registered the pressure of the vapour of the tetrachloride and of the argon of which it was mixed. Careful measurement of the pressure was made before commencing the experiment, and after its completion. Although a considerable amount of other chlorides of carbon was produced, no alteration of pressure was noticeable; the liberated chlorine having been absorbed by the mercury present. Here again the argon did not enter into the reaction, but it was recovered without loss of volume.

The remaining experiments relate to attempts to produce compounds of helium. The plan of operation was to circulate helium over the reagent at a bright red heat, and to observe whether any alteration in volume occurred—an absorption of a few c.c. could have been observed—or whether any marked change was produced in the reagent employed. As a rule, after the reagent had been allowed to cool in the gas, all helium was removed with the pump, and the reagent was again heated to redness, so as, if a compound had been formed, to decompose it and expel the helium. Every experiment gave negative results; in no case was there any reason to suspect that helium had entered into combination.

A short catalogue of the substances tried may be given, none of which gave any signs of combination.

(4) Sodium.	(13) Thorium.
(5) Silicon.	(14) Tin.
(6) Beryllium.	(15) Lead.
(7) Zinc.	(16) Phosphorus.
(8) Cadmium.	(17) Arsenic.
(9) Boron.	(18) Antimony.
(10) Yttrium.	(19) Bismuth.
(11) Thallium.	(20) Sulphur.
(12) Titanium.	(21) Selenium.

(22) Uranium oxide, mixed with magnesium dust, was heated to bright redness in helium. No change, except the reduction of the oxide, took place. The mixture was allowed to cool slowly in the current, and the helium was removed with the pump till a phosphorescent vacuum was produced in a vacuum tube communicating with the circuit. The mixture was reheated, and no helium was evolved, not even enough to show a spectrum. The vacuum remained unimpaired.

It had been hoped that elements with high atomic weight, such as thallium, lead, bismuth, thorium, and uranium might have effected combination, but the hope was vain.

(23) A mixture of helium with its own volume of chlorine was exposed to a silent discharge for several hours. The chlorine was contained in a reservoir, sealed on to the little apparatus which had the form of an ozone apparatus. No change in level of the sulphuric acid confining the chlorine was detected after the temperature, raised by the discharge, had again become the same as that of the room. Hence helium and chlorine do not combine.

(24) Metallic cobalt in powder does not absorb helium at a red heat.

(25) Platinum black does not occlude it.

(26) It is not caused to combine by passage over a mixture of soda-lime and potassium nitrate heated to bright redness. This was hardly to be expected, for it resists the action of oxygen in presence of caustic soda, even when heated by the sparks which traverse it.

(27) A mixture of soda-lime and sulphur consisting of polysulphides causes no change of volume in a current of helium passed over it at a bright red heat.

(28) Induction sparks in an ozone apparatus passed through a mixture of helium with benzene vapour in presence of liquid benzene for many hours, gave no change of volume. The benzene was, of course, altered, but the sum of the pressures of the helium and the benzene-vapour remained as at first. Had helium been removed, contraction would have occurred.

This ends the catalogue of negative experiments. Any compound of helium capable of existence would probably be endothermic, and the two methods of producing endothermic compounds, where no simultaneous exothermic reaction is possible, are exposure to a high temperature, at which endothermic compounds show greater stability, and the influence of the silent electric discharge. These methods have been tried, so far in vain. There is, therefore, every reason to believe that the elements, helium and argon, are non-valent, that is, are incapable of forming compounds.

Chemical Society, May 21.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read. The diphenylbenzenes, I. Metadiphenylbenzene, by F. D. Chattaway and R. C. T. Evans. Metadiphenylbenzene may be prepared by the action of melted sodium on a boiling xylene solution of metadichlorobenzene and chlorobenzene; it melts at 84°.—Derivatives of camphoric acid, by F. S. Kipping. A lactonic monocarboxylic acid, $C_{10}H_{14}O_4$, which the author terms trans-π-camphanic acid, is obtained by boiling sodium π-bromocamphorate with water; its cis-isomeride can only be prepared as a salt. On oxidising trans-π-camphanic acid, transcamphotricarboxylic acid $C_{10}H_{14}O_6$ is obtained; on fusion with potash it yields the isomeric ciscamphotricarboxylic acid.—On some substances which exhibit rotatory power both in the liquid and crystalline states, by W. J. Pope. Cis-π-camphanic acid and transcamphotricarboxylic acid possess the power of circularly polarising light, both in the dissolved and crystalline state; in the former case the circular polarisation in the crystalline state is a specific property of the crystalline structure, but in the latter it is due to complicated twinning of the crystals.—Dimethoxydiphenylmethane and some of its homologues, by J. E. Mackenzie. Dimethoxydiphenylmethane, and the corresponding diethoxy- and dibenzoxy-compounds, may be prepared by the interaction of benzophenone chloride and the sodio-derivative of methylic, ethylic or benzylic alcohol respectively.

Zoological Society, June 2.—F. DuCane Godman. F.R.S., Vice-President, in the chair.—Mr. Sclater exhibited the skin of an African Monkey of the genus *Cercopithecus*, originally received alive from Mombasa, which he believed to be referable to Stairs's Monkey (*C. stairsi*).—Mr. Sclater also exhibited a series of water-colour drawings of African antelopes by Mr. Caldwell, and a photograph of the gorilla now living in the Society's Gardens, by Mr. Henry Scherren —A communication was read from Mr. Henry J. Elwes and Mr. Edwards, containing a revision of the European and Asiatic butterflies of the family Hesperiidæ. The species treated of in this paper were about 450 in number and were divided into about 100 genera.—Mr. Charles Davies Sherborn gave an explanation of the plan he had adopted in his "Index Generum et Specierum Animalium." Mr. Sherborn stated that the absence of any trustworthy lists of the species of particular genera had led him to commence the compilation of an "Index Generum et Specierum Animalium" in 1890. Since that time 130,000 generic and specific names had been recorded in a manuscript which was stored at the British Museum (Natural History). Mr. Sherborn explained in detail the method and plan adopted for the compilation of the work.—Mr. G. A. Boulenger, F.R.S., read a paper on the dentition of snakes, and added remarks on the evolution of the poison-fangs in this order of reptiles.

PARIS.

Academy of Sciences, June 1.—M. A. Cornu in the chair.—The President announced the loss sustained by the Academy by the death of M. Paul Daubrée, Member of the Section of Mineralogy. A letter from M. Des Cloizeaux, giving a brief account of M. Daubrée's contributions to science, was read by the Secretary.—Note on the observed passages of Mercury across the disc of the sun, and on the question of the existence of inequalities of long period in the mean longitude of the moon, of which the cause is still unknown, and in the rotation of the earth upon its axis, by M. S. Newcomb.—On the laws of induction. Reply to the note of M. Marcel Deprez, by M. A. Potier.—Action of acetylene upon iron, nickel, and cobalt reduced by hydrogen, by MM. H. Moissan and Ch. Moureu. If acetylene, which has been allowed to suddenly impinge upon pyrophoric iron which has been reduced by hydrogen at the lowest possible temperature, the gas is decomposed with incandescence into its constituents. At the same time, owing to the high temperature, condensation takes place, and a liquid hydrocarbon, rich in benzene, is produced. The same phenomenon is produced by pyrophoric nickel and cobalt, and also by platinum black. No compound containing metal can be isolated, and the decomposition appears to be due to physical causes.—Respiratory exchanges, in the case of muscular contractions provoked electrically in animals either fasting, or fed with a diet rich in carbohydrates, by MM. A. Chauveau and F. Laulanie. The experimental results with dogs and rabbits were identical with those already obtained with men.—New experiments on the distribution of velocities in tubes, by M. Bazin. No single expression can be given which will accurately represent the velocity of an air current at any point between the centre and circumference of the tube, the law being very complicated. At a distance from the centre equal to three-fourths of the radius of the tube the velocity was equal to the mean for the whole tube.—On a musical register, by M. A. Rivoire. Description of an instrument for automatically recording the notes struck on a piano.—Density of variable stars of the Algol type, by M. Mérian. Starting with the hypothesis that the variations in the brightness of stars of the Algol type are due to eclipses produced by dark satellites, a formula is developed giving the density in terms of constants that can be experimentally determined.—On entire functions, by M. Hadamard.—On systems in involution of equations of the second order, by M. E. Goursat.—On a differential equation of the first order, by M. Michel Petrovitch.—On the rotation of a variable body, by M. L. Picart.—On the anomaly in the acceleration of gravity at Bordeaux, by M. J. Collet.—On the theory of turbines, pumps, and centrifugal fans, by M. A. Rateau.—On molybdenite and the preparation of molybdenum, by M. M. Guichard. Metallic molybdenum free from sulphur can be obtained by subjecting the mineral molybdenite in a carbon tube to the electric furnace (900 amperes, at 50 volts) for five minutes. The ingot contained about 92 per cent. of molybdenum, 2 per cent. of iron, and 7 per cent. of carbon.—On the methylamines, by M. Delépine. As a means of distinguishing the three methylamines rapidly and with certainty, the formation of the picrates is recommended, the salts from mono-, di-, and trimethylamine melting respectively at 207°, 156°, and 216°, and differing also in colour and solubility.—On the reaction between aldehydes and phenylhydrazine, by M. H. Causse. Compounds are obtained with acetaldehyde and benzaldehyde which appear to contain one molecule of aldehyde to two of phenylhydrazine, and to be formed without any condensation.—On a new building material from glass refuse, by M. Garchey.—On the influence of certain pathological agents on the bactericidal properties of the blood, by M. E. S. London.—On the slowness of the normal coagulation of the blood in birds, by M. C. Delezenne. Contrary to the generally accepted view, if the blood of birds is taken under experimental conditions similar to those in general use for mammals, the coagulation always takes place with extreme slowness, frequently not commencing until four to six hours after its removal from the artery.—On a new audiometer, and on the general relation between the intensity of the sound and the successive degrees of sensation, by M. Charles Henry.

BOOKS RECEIVED.

BOOKS.—Crystallography for Beginners: C. J. Woodward (Simpkin).—Crystals and Apparatus for use with ditto (Simpkin).—Chemistry in Daily Life: Dr. Lassar-Cohn, translated by M. M. P. Muir (Grevel).—The Spas and Mineral Waters of Europe: Drs. H. and F. P. Weber (Smith, Elder).—The Antichrist Legend: W. Bousset, translated by A. H. Keane (Hutchinson).—Lloyd's Natural History. British Birds: R. B. Sharpe, Part 1 (Lloyd).—Théorie Nouvelle de la Vie: Dr. F. Le Dantec (Paris, Alcan).—Stuttering and how to cure it: L. Klindworth (Glasgow, Bauermeister).—A Manual of Botany: Prof. J. R. Green, Vol. 2 (Churchill).—The Pathology of the Contracted Granular Kidney: Sir G. Johnson (Churchill).—Animals at Work and Play: C. J. Cornish (Seeley).—Physikalisch-Chemische Propaedeutik, Zweite Hälfte, 1 Liefg. THURSDAY, JUNE 18, 1896.

THE EVOLUTION OF COUNTING.

The Number Concept: its Origin and Development. By Levi Leonard Conant, Ph.D. 8vo. Pp. 218. (New York and London: Macmillan and Co., 1896.)

PROF. CONANT has produced a book which supplies a gap in scientific literature, and on it he has expended great diligence in collecting the materials, and circumspection in dealing with them. The problems of the origin and development of the number concept are important alike to the anthropologist and the psychologist, and all attempts to connect these two branches of science are most welcome; for the scope of the book, therefore, and for its execution, Dr. Conant is to be congratulated.

In a few instances, languages have been found to be absolutely destitute of pure numeral words; the Chiquitos of Bolivia, for example, expressed their idea for one by *etama*—"alone"—they had no real numerals. A few other South American languages are almost equally destitute of numeral words, but some indirect expression shows a conception of the difference between 1 and 2, or, at least, between 1 and many.

There is a surprising paucity of numeral words among the native races of South America, Australia, New Guinea, and among the Pigmy peoples. Many of these have only two numerals. It is probably true that no Australian language contains a pure, simple numeral for 4; a few tribes have a numeral for 3. The same obtains for the Papuan as opposed to the Melanesian tribes of British New Guinea, whereas the numerals of the latter S. H. Ray, *Trans. Internat. Congr. Orientalists*, London, 1892–93, p. 770) have decided affinities with those of the Melanesian archipelagoes. It is also characteristic of the Australians and the Papuans (as here restricted) to count by pairs; but this is not a Melanesian custom, though it is employed in Polynesia. The Mincopies (Andaman Islands) and the Veddas have numerals for only 1, 2, beyond which they say "and one more, and one more," &c.; for the Bushmen, 3 means simply many. The Pigmies of Central Africa, according to Stanley, have separate numerals up to 6, but the words for 1 (*ujju*) and 6 (*ijju*) are so closely akin, that it suggests that 6 was to them a new 1. These Pigmy people are considerably in advance of the others just referred to, so far as their system of numeration is concerned.

The author carefully points out that it is not a general law that those races which are lowest in the scale of civilisation have the feeblest number sense or the least possible power of grasping the abstract idea of number. If the life of any tribe is such as to induce trade and barter, a considerable quickness in reckoning will be developed among them. In giving 1, 2, 3, 5, 10, or any other small number as a system limit, it must not be overlooked that this limit mentioned is in all cases the limit of the spoken numerals at the savage's command. The actual ability to count is almost always, if not always, somewhat greater than their vocabularies would indicate. By means of their fingers, toes, or other parts of their body, or by the aid of sticks and other objects, the savages with even the lowest number concept can indicate higher numbers than their spoken numbers. Most proceed with more or less readiness as far as their fingers will carry them, and this limit is frequently extended to 20.

The primitive savage counts on his fingers until he has reached the end of one, or more probably of both, hands. Then if he wishes to proceed further some mark is made, a pebble is laid aside, a knot tied, &c., to signify that all the counters at his disposal have been used. Then the count begins anew, the terms already used are again resorted to, and the name by which the first halting-place was designated is repeated with each new numeral; hence *thirteen*, *fourteen*, &c. In Teutonic languages the smaller number is prefixed to the base, *e.g.*, *fünf und zwanzig*; but the direct method (*twenty-five*) is far more common, though both are found in all parts of the world.

The formation of numeral words by subtraction, though it seems decidedly odd to us, is of common occurrence. In Latin, 19 is *undeviginti* (1 from 20); the Bellacoola, of British Columbia, say for 19 "one man less 1," as in their numeral scale 20 is "one man," for them 15 is "one foot," and 16 "one man less 4." Many tribes seem to regard 9 as "almost 10," and to give it a name which conveys this thought.

The following Zuñi scale is interesting:—

1, "taken to start with."
2, "put down together with."
3, "the equally dividing finger."
4, "all the fingers but one done with."
5, "the notched off."
6, "another brought to add to the done with."
7, "two brought to and held up with the rest."
8, "three brought to and held up with the rest.
9, "all but all are held up with the rest."
10, "all the fingers."
11, "all the fingers and another over above held."
20, "two times all the fingers."
100, "the fingers all the fingers.

1000, "the fingers all the fingers times all the fingers."

While the savage almost always counts on his fingers, it does not seem at all certain that these words would necessarily be of finger formation. The numerals for 1 and 2 would be formed long before the need would be felt for terms to describe any higher number. Universal as finger counting has been, finger origin for numeral words has by no means been universal. In nearly all languages the origin of the words for 1, 2, 3, and 4 are so entirely unknown that speculation respecting them is almost useless.

The first real difficulty which the savage experiences in counting, the difficulty which comes when he attempts to pass beyond 2, and to count 3, 4, and 5, is of course slight. Beyond 5, primitive man often proceeds with the greatest difficulty. Whenever the fingers and hands are used at all, it would seem natural to expect for 5 some general expression signifying *hand*, for 10 *both hands*, and for 20 *man*. Such is the ordinary method of progression, but some people express 10 by *man*, perhaps because they do not use the toes in counting; thus the Api word for 200 is "10 times the whole man taken 2 times."

Without the establishment of some base, any system of numbers is impossible. A binary system is characteristic of Australia, but it occurs elsewhere; instances of quaternary numeration are less rare than are those of ternary, and there is reason to believe that this method of counting has been practised more extensively than any other, except the binary and the three natural methods—the quinary, the decimal, and the vigesimal. There is probably no recorded instance of a number system formed on 6, 7, 8, or 9 as a base.

In its ordinary development the quinary system is almost sure to merge into either the decimal or the vigesimal system, and to form with one or the other, or both of these, a mixed system of counting. Whether or not the principal number base of any tribe is to be 20, seems to depend entirely upon a single consideration—are the fingers alone used as an aid to counting, or are both fingers and toes used? If the former, the resulting scale must become decimal. The quinary is never the principal base in any extended system. The Celtic races showed a preference for counting by twenties, which is almost as decided as that manifested by the Teutonic races for counting by tens.

With such a vast field from which to collect materials for his study, it is inevitable that Prof. Conant should have overlooked some authors who might have furnished him with additional examples, and that he should have made a few slips. Among the omissions may be noted Dr. Von den Steinen's discussion on the numeration of the Bakaïri in his "Unter den Naturvölkern Zentral-Brasiliens," Mr. Ray's studies in the languages of New Guinea, Mr. H. Clifford's account of the Negritos of the Malay Peninsula (*J. Roy. As. Soc. Straits Br.*, 1892), Dr. S. Günther's study on numerical systems (*Beitr. Anth. Urgesch. Bayerns*, 1890, ix.). On p. 96 the Torres Islands in the New Hebrides are confused with Torres Straits, and the languages of Darnley Island (p. 24) and Warrior Island (p. 107) are Papuan (Torres Straits), and not Australian dialects. Anthropologists would have been thankful if the ethnological aspect of the question had been dwelt upon a little more fully; for example, the ethnologist is not at a loss to account for the superior development of the number sense in the Nicobarese as compared with that of the neighbouring Andamanese. The book is admirably printed, and is packed with valuable information clearly and logically arranged.

A. C. HADDON.

GEOMORPHOGENY.

Leçons de Géographie physique. Par Albert de Lapparent. Pp. xvi. + 590. Illustrations. (Paris: Masson et Cie., 1896.)

If Prof. de Lapparent had been writing in America, he would have introduced the word *Geomorphogeny* in the title of his latest book; but in Europe, he observes in the preface, there is some risk of frightening those whom he would wish to instruct if they are confronted by an unfamiliar term at the outset The title "Lessons in Physical Geography," although quite without terror, is not fairly descriptive, for this fine volume is no ordinary treatise of physical geography in the usual vague sense. "Lessons on the Genesis of Geographical Forms" would, in the author's view, and in ours, be more descriptive; but the full scope of the work would, perhaps, hardly be suggested even by such a title.

Whatever he may call it, a book by Prof. de Lapparent is sure of a cordial reception by students and men of science in all parts of the world, for he combines the traditional grace and charm of French scientific writers with a temperateness of judgment and width of view which, rightly or wrongly, foreigners do not always associate with the writings of his countrymen. The avowed object of the work is to furnish a body of doctrines, logically linked together, which shall help to place geography on a truly rational basis. This basis is, in Prof. de Lapparent's opinion, a geological one, for he argues that the knowledge of no geographical form can be complete unless its antecedent conditions are known, and in geology alone can the clue to these be found. We might perhaps demand an even deeper foundation than geology, by taking into account the relations of form and position and the means of determining these mathematical conditions by astronomical observations: but geology may be freely accepted as the layer in the pyramid of geographical science which comes immediately below physical geography, and is most indissolubly connected with it.

The volume takes the form of twenty-five "lessons" or chapters; but it may be divided into two parts, approximately equal in bulk—the enunciation of the general principles of geomorphogeny, and the application of these to the configuration and structure of each of the continents. The great lines of terrestrial relief are first outlined, and the conditions of land-modelling are then discussed in fuller detail and with a more comprehensive grasp than in any other book of the kind with which we are acquainted. The various agencies at work on the land-surface are treated in turn, and their action illustrated by a great wealth of instances. The normal course of erosion in a region is first explained, and the various complications introduced by structural conditions, classed as genetic and tectonic, are then introduced. Genetic conditions are those produced by the original formation of the portion of land under consideration, *e.g.* whether sedimentary, igneous, or glacial; tectonic are those subsequently produced by movements of the crust. Considering the predominant part played in the modelling of the land by running water, it is natural that several lessons should be devoted to this agency, in the discussion of which a prominent place is given to the view of the cycle of erosion so vigorously set forth of recent years by Prof. W. M. Davis, of Harvard. One can hardly say of any part of this theory that it is new. Geologists have worked so long at the phenomena of erosion, that it is now difficult to fit each stage of the process with the name of the first observer or theoriser. But there is no doubt that, however universally the knowledge of the processes of the origin of scenery by denudation were known, the credit for expressing the nett result of them in terse and appropriate language is due to Prof. Davis, and his mode of statement is accepted by Prof. de Lapparent with full acknowledgment. The conception of the origin of surface features through a process of evolution, a continuous succession

of adaptations to environment, is clearly stated; and the view of a land-surface modelled by the action of its rivers, and passing through the consecutive stages of adolescence, maturity, old age, and decrepitude, with a possible rejuvenescence by partial upheaval during the later stages, is set forth in an attractive manner. This is perhaps the nearest approach to a theory of physical geography which has yet been advanced, and the results of applying it serve to invest with fresh interest the monotonous topography of regions which, having run their course of natural life, await in the condition of a "peneplain" the revivifying tectonic power which will start their old sluggish rivers into fresh activity, throwing them out of harmony with their surroundings, and setting them to work to dig, carry, and build until they have created a new land, and, as is the way of the world, again destroyed it.

Looking on a river as an individual, or rather as a living system, any change in one part is shown to affect the whole. For example, the slow cutting down of the outlet of a lake, the surface of which serving as a base-level has dictated the configuration of the country above, lowers the level, accentuates the upper slopes, quickens the tributaries one by one, causing them to erode their valleys more vigorously, and in time perhaps to work back and tap the affluents of some other system, reversing their flow and extending the sphere of the power of the main river. The continual adaptation of river to land may in large measure be taken as the key to the origin of scenery in regions of normal drainage.

Prof. de Lapparent does not view aqueous erosion as all-powerful; he gives great weight to tectonic changes in preparing the way and laying down the lines along which erosion is to act, as, for example, in outlining the depressions of fjord and lake valleys. To glaciers he assigns a comparatively humble place: they cannot dig, but they are excellent polishers, and inexhaustible carriers; while if they cannot make valleys, they may at least preserve them unfilled for future occupation by lakes. The treatment of regions of internal drainage with their arid climates and characteristic æolian land-forms is particularly good.

We cannot, of course, attempt to summarise here a volume of six hundred pages, in which there is a steady unfolding of a definite plan supported by innumerable examples. It is only possible to allude to the chief contents. After the geomorphogenic introduction, two lessons are given to geological principles and their application in palæogeography, or the reconstruction of the map of the world in past ages. This introduces the systematic description of Europe, and of the other continents in less detail, from the point of view of the origin of their land-forms. Although necessarily in general terms, the description is sufficiently full to give a fair idea of the origin of all the more striking features of mountain and plain, and the general hydrographic system. There are points which might be criticised in detail; for example, one of the most important features in the existing geography of Scotland—the 25-foot raised beach which forms the sites of almost all the coast towns, both on the east and west—is not mentioned, but the larger features are very clearly described.

The work of M. de Lapparent builds largely upon the foundations of Suess, Penck, Richthofen, and numerous British and American geologists whose contributions to knowledge are carefully acknowledged. It is emphatically a book for teachers and for students of geography; a model of strong and clear reasoning in the elaboration of a theory where no theory was generally recognised before, and a rich storehouse of facts and references full of suggestiveness, and affording evidence of the widest reading and the most careful thought.

HUGH ROBERT MILL.

THE RESEARCHES OF NEWELL MARTIN UPON THE HEART AND RESPIRATION.

Physiological Papers. By H. Newell Martin. Reprinted as Memoirs from the Biological Laboratory of the Johns Hopkins University. III. 4to. Pp. 264. (Baltimore: Johns Hopkins Press, 1895.)

THE Johns Hopkins University at Baltimore was founded in the year 1876, and Newell Martin left Cambridge, to the personal regret of all his English friends, to become the first occupant of the chair of Biology. This he held during seventeen years, in the course of which the department over which he presided grew from small beginnings to large and extensive laboratories fully furnished with apparatus, animals and privatdocents in the most up-to-date Teutonic style. In the summer of 1893, Prof. Martin was compelled by ill-health to resign his professorship, and in recognition of the value of his work, and as a token of their affection and esteem for him, his American friends and pupils have republished the scientific papers and some of the public addresses which were written and delivered by him during his tenure of the chair.

Most of the work done by Prof. Martin during this period is upon the action of the mammalian heart, and the papers upon this subject occupy nearly one half of the volume. As all physiologists know, Martin was the first to carry out with success experiments upon the action of the isolated heart of the mammal, most of our knowledge regarding the isolated heart having been derived from experiments upon cold-blooded animals. It was not to be expected that there would be any serious divergences in the mode of action of the heart in the two cases, and in fact the results which Martin and his pupils obtained regarding the effects of pressure of temperature and of drugs were such as might probably have been anticipated. Nevertheless it marked a distinct advance in what the Royal Society officially terms "natural knowledge" to have succeeded in determining these points in the mammal, and that Society set the stamp of its recognition upon the work by selecting one of the most important of these papers as the Croonian lecture for 1883.

The other researches relate exclusively to the mechanism of respiration in the frog and in the mammal. The peculiar character of the respiration in the former animal has always excited the interest of physiologists, and in more recent years it had been studied graphically by Paul Bert and Burdon-Sanderson. Martin subjected the normal respiratory movements in the frog to a careful examination, and arrived at con-

clusions of much interest. He was also able to show, both in the frog and mammal, the influence of the mid-brain upon those movements.

One of the most important pieces of work here recorded is that in which Martin experimentally determined that the internal intercostal muscles are expiratory in their function throughout their whole extent, thus finally settling a question which had divided physiologists ever since physiology was recognised as a science. This he was enabled to do not by experiments upon models, nor upon the cadaver, but by direct observation in the living animal; a method which will always remain the only satisfactory one for solving such problems.

The physiologists of this country owe a debt of gratitude to their American colleagues for having provided them in so handsome a form with this important collection of monographs. E. A. Schäfer.

OUR BOOK SHELF.

Atlas d'Ostéologie. Articulations et Insertions Musculaires. By Prof. Ch. Debierre. Pp. viii + 92. (Paris: Alcan, 1896.)

This atlas contains 88 plates with 251 figures illustrating the human skeleton. Figures are also given to illustrate the ligaments of the various joints, and, further, for each bone the muscular attachments are indicated by red printing. The mode of development and microscopic of bone are illustrated by five figures, and in a few cases a certain amount of comparative osteology is introduced. The figures are by no means better than those given in the standard text-books, and it is a pity that no mention is made in each case of the amount of reduction or magnification made in the drawing. Some of the figures are very confused, and the individual parts difficult to recognise. This is especially the case with such figures as the base of the skull with the soft parts left attached (Fig. 82). In many cases it seems a mistake that the figures have not been drawn on a larger scale, as much room is often wasted on the plates.

Mechanics for Beginners. By W. Gallatly, M.A. Pp. 253. (London: Macmillan and Co., Ltd., 1896.)

The special characteristics of this book are stated to be (1) the large number of examples—eight hundred—of which one hundred and sixty are worked in full; (2) the great attention given to work, power and energy; (3) the classification, in small sections, of problems of the same type, the method of dealing with each section being explained by a worked example. Teachers of elementary theoretical mechanics will know how to appreciate these important qualities of the book. The descriptions are very clear, and the diagrams are helpful. The student who uses the treatise as a text-book, familiarising himself with the illustrative examples, and working through only a part of the well-selected and comprehensive exercises, will be equipped for almost any examination in elementary theoretical mechanics. And he will, at the same time, lay up in his mind a fund of useful knowledge.

Engineer Draughtsmen's Work. By a Practical Draughtsman. Pp. 96. (London: Whittaker and Co., 1896.)

Students in technical schools will find in this book a number of valuable hints on the use of mathematical instruments and the work of drawing-offices. The information is very elementary, but its character is such that it will train young draughtsmen to be accurate and methodical in their work.

Forty-eight pages of advertisement are bound up with the ninety-six pages of text.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Flying Engines.

In the summer of 1893, I made some experiments on the effect of steam-jacketing small steam-engine cylinders by placing the whole of the cylinder and valve chest inside the boiler; the increase of economy was so marked, that I was led to try whether a small toy engine could be made to sustain its own weight in the air by the lifting power of an air screw on the crank-shaft.

Fig. 1 shows this little engine. The boiler is of seamless steel $2\frac{1}{2}''$ diameter, $14''$ long, and $\cdot01''$ to $\cdot015''$ in thickness; the steam cylinder, single acting, $1\frac{1}{4}''$ diameter by $2''$ stroke, and about $\cdot03$ thickness of tool steel; the piston is of thin cup form, also of tool steel; the admission valve is cylindrical, $\frac{6}{16}''$ diameter, cutting off at $\frac{3}{4}$ stroke. The whole of the valve and cylinder are within the boiler. Some parts of the engine were soft soldered, and some hard soldered; the screw is of cane covered with silk. The working pressure was limited to about 50 lb. per square inch. The total weight of the apparatus, with water, as in Fig. 1, is $1\frac{1}{4}$ lb.

Fig. 1.—Steam engine and boiler working lifting screw; large plane to prevent rotation of boiler; total weight $1\frac{1}{4}$ lb. I.H.P. developed, $\frac{1}{4}$. Raised itself about 12 feet in the air, with steam contained in boiler. No firing after start. Initial pressure 50 lb. Maximum revolution about 1200 per minute.

Steam was raised by placing the boiler over a spirit-lamp, and when 50 lb. was registered on the gauge, and the engine started, it raised itself in the air vertically to a height of several yards. The revolutions of the engine were about 1200 per minute, and the i.h.p. $\frac{1}{4}$ horse-power.

The same engine was then mounted on a framework of cane, covered with silk, forming two wings of 11 feet span, and a tail, the total area being about 22 square feet. The total weight was now $3\frac{1}{2}$ lb., and when launched gently from the hand in an inclined horizontal direction it took a circular course, rising to a maximum height of about 20 feet. When the steam was exhausted, it came down, having traversed a distance of about 100 yards.

Fig. 2 shows the machine in mid-air. The photographs were taken by Mr. Gerald Stoney.

Considering the primitive construction of the apparatus, the result clearly showed that flights of considerable distance, possibly some miles, were quite possible with a small economical steam-engine mounted on aeroplanes.

The boiler was also found to be able to steam the engine continuously by using methylated spirits intead of water in the boiler,

and burning the exhaust as fuel; but when in flight, the force of the wind extinguished the flame.

It was clearly seen by the experiment that for practical commercial success of this class of steam apparatus an air condenser is essential, as the weight of water used in a few minutes' run

FIG. 2.—Same engine and boiler as before, attached to two inclined wing planes, and tail. From tip to tip of wings 11 feet; total surface of wings and tail about 22 square feet. Total weight of whole apparatus 3½ lb. Steam raised to 50 lb. per square inch, and started. Length of flight about 100 yards on level; maximum height during flight, about 20 feet. The propelling screw is seen in front and above the frame.

equals the total weight of engine and boiler. Without a condenser, the length of flight must necessarily be limited to a very few miles, and it would seem that the chief problem that workers in this field have to solve, is to obtain an efficient and light dry air condenser. CHARLES A. PARSONS.

Heaton Works, Newcastle-on-Tyne.

Experiments on Röntgen Rays.

AFTER examining the fluorescent and photographic action of the rays (X_2) emitted on strongly *heating* a "focus tube," and finding them different to the rays which have been hitherto noticed (X_1), in that the relative transparency of flesh, bone, aluminium and glass differs for the two kinds of rays, it seemed desirable to try the effect of cooling the tube. Solid carbon dioxide and ether, and then solid carbon dioxide alone were employed, with the result that in both cases the fluorescence of screen and tube very rapidly died out and the current apparently failed to pass through the latter; as the tube gradually grew warm again, the fluorescence in it returned, not gradually, but very suddenly, at a temperature not very far below that of the room, the glass lighting up brilliantly, and the shadows of the bones showing on the screen with increasing distinctness. The emission of X_1 rays reaching a maximum at about 12° C. (a rough guess). On further heating X_2 rays begin to be evolved, judging from the increasing opacity of the flesh, whilst at the same time the fluorescence excited on the screen grows rather brighter, until the state recorded in my paper of June 4, is reached. As the condition for the maximum of X_1 rays probably varies to a certain extent with the different forms of tube, and even different specimens of the same kind of tube, with the degree of exhaustion, &c., it seems to follow from these experiments that in some cases warming the tube slightly might be useful in photographing the bones, whilst in others moderate cooling would be better; and from the accounts of various operators such would seem to be the case, though, as will be seen in the light of subsequent experiments, the particular method of heating or cooling is an important factor in the result. Solid carbon dioxide seemed very opaque to the rays when its low density is considered, but the effect may have been partly due to the frost condensed upon it from the air.

Wishing to verify for myself the results of other experimentalists, I next examined the tube for its action on a well-insulated brass plate, at first by connecting it with a sensitive electroscope, and afterwards with one of the standard Thomson's quadrant electrometers. As the experiments were all carried out with great care, it may be worth while to state that, using thin aluminium plate well earthed by soldering to a gas-pipe to screen the plate from all ordinary inductive action, the results were that the rays after penetrating $\frac{1}{16}''$ of aluminium, discharged the plate completely, whether electrified positively or negatively, leaving no charge; and that if the plate were uncharged to begin with, it remained uncharged. This result is contrary to that observed by some; but from the delicacy of the instrument used, and the great distance between mirror and scale, there is little room left to doubt the accuracy of this result.

I also tried the effect on a radiometer, making similar experiments with a lampblacked Leslie's cube at about 94° C., and a candle, to see how far radiant energy from these sources was capable of penetrating the large aluminium screens used, in case any heat action might interfere with or mask the effect, and found, as others have, that when perfectly screened from all other action, the radiometer is entirely unaffected by the Röntgen rays, whether they be from a hot or a cold tube. The X-rays are also without action on the blackened face of a thermopile connected with a very sensitive galvanometer.

When the ordinary inductive effects of the tube were *not* screened, I found that the space external to the tube was at a high positive potential, which increased up to contact with the glass of the tube, and was of the same sign all over the bulb part. The cold bulb acted like a positively charged conductor whilst the discharge was passing, and attracted the radiometer arms just as any other charged body would, the effect lasting some time after the discharge stopped. The *unscreened* cold bulb also partly discharged the insulated plate, if the latter were strongly positively charged, it more rapidly discharged it when negatively charged, and left it with a positive charge of the same magnitude to begin with as that left when the plate was strongly positively charged, and lastly in the uncharged plate it developed a positive charge, again of the same magnitude; and this is what would naturally follow from the combination of the Röntgen rays effect with that of ordinary induction.

The X_2 rays seem to discharge a charged plate whether positively or negatively charged, but of this I cannot at present feel quite sure. Aluminium seems so far opaque to them that it is doubtful whether, when a screen is used, any of the rays get through, and when a screen is not used, one cannot feel certain that the effect observed is due to the X_2 rays either wholly or partly. After heating the tube and turning on the current, the whole tube is filled with a whitish, lavender-coloured light, which comes to a focus on the glass behind the kathode, above or below it; and whilst in this state and giving little or no fluorescence on the screen, the tube does *not* charge an *unscreened insulated plate*, but it does rather rapidly drain it of a previously communicated charge, either positive or negative. As the tube cools the lavender light retreats more and more from the kathode till at last it reaches the upper edge of the rectangular anode, when the positive charge, mentioned before, begins to be given to an uncharged insulated plate, but very slowly; as soon as the centre of the anode is bare of the lavender discharge, the potential of the unscreened plate very rapidly rises, and by the time the whole anode is clear of the lavender light the normal positive charge is re-established on the insulated plate. When the lavender glow retires from the kathode, it leaves behind it a space full of almost invisible light, which excites whitish green fluorescence on the glass of the bulb, and it is during this time that most of the rays are X_2, as is shown by the fluorescent screen, and photographs of a hand. I have not yet followed out the changes, relative and absolute, of potential of the anode and kathode, but it would seem almost certain that during the life of the lavender glow the whole tube acts as a relatively good conductor up to the time when the lavender glow crosses the centre of the anode—or the point where the axis of the kathode mirror cuts the anode, when there is an abrupt decrease in conductivity. I intend to investigate this point as soon as possible, and meantime pass on to what I imagine will prove of great use and interest to all who work with these tubes.

During some experiments on the tube with an 18" Wimshurst machine, I noticed that the X_1 rays, *i.e.* those showing the bones best, seemed to be emitted or not according as a brush discharge occurred on the wire leading to the anode of the tube, close to the tube, or not; and that the "electric wind" which blows from the tube as from all charged bodies, seemed also to vary in intensity with the X_1 ray flashes, the X_1 rays being most copiously emitted apparently at the moment when the brush discharge ceased or the wind moderated. I soon found that by making a small brush on the wire near the anode, or drawing

one with the finger from various parts of the tube (but not from all), best from the circular section of the tube in a plane with the edge of the kathode mirror, or in the very immediate neighbourhood of this line, the discharge producing the X_1 rays could be induced at will in a tube which was not otherwise giving them, or at any rate only giving them very feebly. Thinking, therefore, that the production of the X_1 rays must be in some way connected with intermittent leakage of the charge which resides on the outside of the tube (a continuous drain stops fluorescence and the emission of any rays capable of exciting my fluorescent screen altogether), I tried various ways of drawing off this charge intermittently, with several curious results; but the plan I find to work best is to place a ring of plain copper wire round the tube in the plane of the kathode mirror's edge, not touching the glass, but very near it, and then to cause a very rapid but intermittent discharge by bringing a wire connected to earth within a *very small* distance of some part of this ring, so far I cannot discover any particularly favourable position. The sparks between this ring and the earth wire are very small, but the effect on the fluorescent screen exceedingly striking.

What is still more interesting is that not only is the discharge of X-rays made much more regular (when the adjustment of the ring and wire is carefully made), but *the X-rays can thus be induced in a tube with a far weaker current;* the weakest current capable of inducing sparks between the ring and conductor seems capable of giving the X-rays, though they are more copiously emitted with a stronger current.[1] And not only so, but the tubes I have experimented with seem to show as yet no symptoms of growing fatigued. I have caused a brilliant emission of the X-rays from a tube which was before "fatigued"—at least, my coil seemed too weak to excite it, and the emission of X_1 rays has been sustained for over two hours with but a few short intervals, without showing any signs of diminution, judging by the screen effects; but on the withdrawal of the ring and wire, it at once failed to give any. This seems an important result, for it must greatly shorten the exposure and fatigue necessary for the photography of thick objects, and also greatly save the expense of the operations. Even breathing very gently, or blowing gently for a moment on the tube, specially on the parts mentioned, produces a marked bright flash which on examination will prove very rich in X-rays (a fact first noticed by Mr. P. H. Walter, my assistant). It would seem to follow from this that the "fatigue" is not altogether due to the diminution of the number of free particles in the tube, but to a kind of polarisation in which the glass acts as the dielectric separating a negative charge inside from a positive outside, the X-rays and fluorescence being dependent in some way on the oscillations consequent on the intermittent discharge of this condenser. I find that the tube also gives X-rays plentifully (though not so plentifully as when *both* terminals of the secondary circuit are used), when the positive terminal of the coil is connected in the usual way, and a wire from earth leads to what is usually the kathode; but only, so far as my experiments go, when the ring and other earthed wire are used. In this experiment the negative terminal was *not* connected with the earth, but insulated. The tube did not give X-rays, scarcely indeed any sign of the passage of electricity when the kathode wire only was retained in its usual position. The positive anode therefore seems in some respects to govern the emission of these rays.

In one experiment I placed a ring round the glass in the plane of the concave mirror of a Crookes' tube showing the "independence" of the positive pole from which I could not get any X-rays, and found on extracting a series of small sparks from it, with a wire leading to earth, a very decided increase in the still general fluorescence of the tube, but it gave no rays. Incidentally it was noticed that when a wire brush connected to earth was pressed lightly against the glass over the dark spot opposite the kathode, in every place touched by the wire, a most brilliant green fluorescence was excited, which faded away very quickly when the brush was withdrawn. It is therefore certain that much may yet be done to increase the efficiency of the tubes used for the production of X-rays by a further study of the action of neighbouring conductors upon them, and it seems that such a study cannot fail to throw light upon the cause of these hitherto unexplained phenomena.

Eton College, June 8. T. C. PORTER.

[1] I have succeeded in eliciting feeble X-rays from a Newton's focus tube with a small coil giving only 1/3rd of an inch spark—using the ring and earthed wire or finger.

Addendum, June 13.—After trying various forms of conductor, coating different parts of the X-ray tube with Dutch gold, and aluminium leaves, I find the following a most effective plan, and feel no hesitation in recommending it. First coat the external part of the tube between the kathode wire loop and the afore-mentioned plane of the edge of the kathode mirror, with any conducting metallic leaf; being careful that none of it projects beyond the trace of this plane on the glass of the tube. Next coil a stout piece of copper wire into a circular loop with a stem, and place it so that whilst the loop is in the plane of the edge of the kathode mirror, it does not touch either the glass of the tube or the metallic coating—I find an interval of about the $\frac{1}{20}$th of an inch answers excellently; and lastly, instead of using a wire to earth, bring the stem of the looped wire, or better still, a more pliable piece of wire connected with the loop stem, within a very short distance of the part of kathode wire from the coil close to the tube. The adjustment is easily made in practice, and the emission of X_1 rays which follows will, I think, be found satisfactory, to say the least, especially when it is remembered that without the looped wire the tube may be giving no X-rays at all.—T. C. P.

Koch's Gelatine Process for the Examination of Drinking-Water.

I DO not find that Dr. Percy Frankland advances any substantial evidence in his letter of May 12, in support of his broad and unqualified claim that he was the first person in this country who adopted the Koch method and applied it to the London water supply.

Dr. Percy Frankland states that he has "failed to find in Dr. Angus Smith's publications any mention whatsoever of cultivation on plates or their equivalents in any shape or form," and which he "holds to be the essence of the process which bears the name of Koch, and to which modern bacteriology is so profoundly indebted."

Now if Dr. Percy Frankland will turn to page 28 of Dr. Angus Smith's report to the Local Government Board, he will find Dr. Angus Smith writing as follows:—"It may be better to give up test-tubes entirely—equally good results have been obtained by using other vessels." As a matter of fact, photographic glass-plates were used in some of Dr. Angus Smith's experiments, also flat-bottomed flasks, desiccators, &c.; consequently if Dr. Percy Frankland's contention is correct, that the essence of the process which bears the name of Koch consists in the use of plates or their equivalents, Dr. Angus Smith at all events can be credited with having adopted the essence of the process. The main value, however, of Dr. Koch's invention was in the use of gelatine for preserving, as Dr. Angus Smith said, "the indications of organic vitality, and of affording an opportunity for the expansion of living germs in water, keeping a record for a time both of the quality and intensity of life in the liquid, and enabling the smallest points to exert their energies, and, as it were, to build their structures, the size and numbers of which can to some extent be measured and counted"

Dr. Koch was the first to use gelatine, and it was from him Dr. Angus Smith learned its use; for he says, "I seized on the use of gelatine with great earnestness, and soon satisfied myself that there was much to be gained by its use. . . . Dr. Koch has himself informed me that he is glad I have taken up the subject . . . a subject being more fully developed under Dr. Koch by Dr. Rozahegyi, and chemists must prepare for a new condition of things."

With regard to Dr. Percy Frankland's statement that Dr. Angus Smith distinctly deprecated rendering the medium more nutritive, I do not agree with it, inasmuch as Dr. Angus Smith clearly stated that "experience must discover whether this is an advantage . . . the use of sugar in addition to the gelatine renders the examination of water by this method less dependent on the opinion of the operator, and a photograph may be taken of each specimen, and the result preserved as evidence."

Whilst wishing in no way to detract from the value of the work which has been done by the use of the modified Koch's process, and from developments of bacteriological methods since the investigation of Dr. Angus Smith, I believe that I have quoted sufficient evidence to show that Dr. Angus Smith was the first chemist in this country who "seized on" and applied to practical purposes Dr. Koch's gelatine process of 1881; and his name will ever be associated with the historical development and application of Koch's gelatine process in this country; and

as the pioneer worker in the bacteriological method for the examination of drinking-water involving the use of solid culture material, viz. gelatine. FRANK SCUDDER.

Ellerslie, Alderley Edge, June 5.

A Prognostic of Thunder.

As the thunderstorm season has now set in, may I call the attention of weather observers to what seems to me an almost infallible prognostic of thunder, which was described in a letter in NATURE of July 5, 1888.

It consists in the formation of a small group of *parallel streaks* of cloud, seldom more than three or four in number, definite in form, and limited in extent and duration, appearing either as white streaks on the blue, or more rarely as darker streaks against nimbus or cumulo-nimbus.

I have very rarely seen these "parallel bars," as I have come to call them, without their being followed by thunder within twenty-four hours.

As the value of the prognostic seems to depend on the definiteness, small magnitude, and short duration of the "bars" (since one may sometimes see a large portion of the sky covered with rippling clouds which are followed only by rain without thunder, or not even by rain), their connection with thunderstorms seems to be explicable by the view that they are "interfret clouds" of very limited extent, indicating the superposition of atmospheric strata of very unequal temperature or humidity, with a *restlessness* which shows itself in local and temporary irruptions from one stratum into the other; an irregular condition very likely to be associated with electrical disturbance.

I may add that these "bars" are very readily detected after being once seen, and very easily noted; and they deserve, I think, more attention from meteorologists than they have received. B. WOODD-SMITH.

Hampstead Heath, N.W., June 10.

Tufted Hair.

I HAVE had, within the past few days, my first opportunity of examining closely the living head and hair of the African Negro, on several "Kru boys" from the West Coast. Their hair, which was cut moderately short, presented the usual appearance of a congeries of tufts arranged in a more or less linear manner, but when closely investigated it was found to be uniformly distributed over the scalp—each cork-screw tuft, resulting from the separate hairs on amall adjacent areas, intertwisting together and forming a silky compressed curl. In New Guinea I investigated the manner of growth of the hair on a large number of natives from widely distant regions, on many of whom the body was also covered with, to all appearance, little distinct spirals. On close scrutiny, and with a little trouble, these "cork-screws," both on head and body, could be perfectly uncurled and separated out into individual hairs growing from roots as nearly as possible equidistant from a central hair, round which the others coiled themselves, each hair being in fact a twining-plant-like structure, laying hold of a neighbouring hair as a supporting stake. Both on body and head the hair follicles were evenly distributed. These facts, as regards the African, are already quite well known from the investigations of Prof. Virchow and others; but it may not be without interest if I record, after this opportunity of comparing the Melanesian with the Negro, that the growth of their hair in both races is identical.

The Museums, Liverpool, June 14. HENRY O. FORBES.

LORD KELVIN.

AS these words are being printed, the Jubilee of Lord Kelvin's professorship is being celebrated in the most enthusiastic and magnificent manner at Glasgow. Delegates from all parts of the world are present, and among them are many of the most eminent representatives of science at home and abroad. From Paris to Moscow, Canada to Mexico, India to Australia, the whole civilised world unites in congratulating Lord Kelvin on the great work for science and the good of his fellow men which he has achieved, and in offering good wishes that he may have health and strength for the continuance of his glorious career. Though for fifty years he has been Professor of Natural Philosophy at Glasgow, has seen pass through his classes several generations of students, has been one of the greatest leaders in what has been pre-eminently a century of scientific discovery and advancement, has worked as few men can work, and withal has taken the keenest interest in all that ought to interest the true citizen of a great country, yet is his eye not dim, nor his natural force abated. It is the hope of all his friends, and of all the great army of scientific workers, who now are unanimous in doing him honour, that he may have before him many long years of happy and successful work.

Lord Kelvin, though born in Ireland in 1824, began his connection with Scotland and with the University of Glasgow at a very early age. His father, Professor James Thomson, still remembered by many alumni of Glasgow as a remarkably skilled and successful teacher, was appointed to the chair of Mathematics in 1832, so that when only eight years of age, William Thomson began his residence at the University of Glasgow. Only two or three years later he began to attend University classes, and soon attracted attention by a brilliance of intellect very remarkable in one so young. His proficiency in mathematics and natural philosophy was very great, but other studies were by no means neglected, and, under the careful supervision of his father, he received a thoroughly all-round and complete education. It may be mentioned here, that of the importance of giving its due place to science in any good scheme of liberal education, no one could be more convinced than Lord Kelvin, but that no one values more highly than he does the Old Humanities, and the importance of a sound logical and linguistic training.

While he was yet a boy, his interest was keenly excited by such subjects as the Figure of the Earth and Fourier's Theory of the Flow of Heat. On the first he wrote a University prize essay, and, on the latter, a series of papers in which he successfully defended Fourier's researches from a charge of unsoundness which had been brought against them, through some strange misconception, by a very competent writer who had graduated a few years before with the utmost mathematical distinction. It is worth relating, as indicating the promise and power of the youthful natural philosoper, that when only fourteen or fifteen years of age he read Fourier's great treatise through in the intervals of travelling about, during a fortnight's visit to Germany. That he did so to some purpose is shown by the papers in defence, explanation, and extension of Fourier's results, which soon after flowed from his pen.

There can be no question that, like many other eminent physical mathematicians, Lord Kelvin has been inspired and directed by his early study of Fourier and the other great French mathematical writers of the end of the eighteenth and the beginning of the present century. But he has always fully and gratefully acknowledged the helpful and interest-exciting influence of some of his old teachers at the University of Glasgow. To mention only one, Dr. J. P. Nichol, formerly Professor of Astronomy in the University, the compiler and, to a great extent, the author of Nichol's "Cyclopædia of Physical Science," and a most delightful lecturer on astronomical and physical subjects.

The tale of Lord Kelvin's achievements at Cambridge has been often told—how he won the first Smith's Prize and the Colquhoun Sculls, and was known as one of the most promising original mathematicians of the time. He returned to the University of Glasgow as Professor of Natural Philosophy in 1846, and from that day to this the history of his life-work has been in no small measure the history of the progress of physical science. There is no department of physical science which he has not enriched and extended by his discoveries. There is hardly any theory in dynamics, heat,

or electricity, of which his theorems, experimental discoveries and views, do not form a great and fundamental part, and in the domain of physical optics he has recently shed much light on some of the most recondite and disputed questions by his lectures and papers on the subject of the dynamics of systems, of molecules, and the constitution of the ether. To discuss his career in detail would take us too far at present, and we must refer our readers to the article in our "Scientific Worthies" series, which appeared in vol. xiv., p. 385, 1876, and defer an account of his later scientific work to another opportunity.

The accompanying engraving of the University of Glasgow shows the scene of the Jubilee Celebration. The part between the main entrance and the western gateway on the left is the physical laboratory, and the gable of Lord Kelvin's house is shown on the extreme left. A great suite of rooms, all on one level, consisting of the University Library, the Hunterian Museum, the Bute and Randolph Halls, and the Senate Room Lobbies and Examination Hall, give perfectly unique soirée accommodation, in which about 2000 guests assembled on Monday evening. In the Library has been arranged an interesting exhibit of Lord Kelvin's inventions and instruments, with the diplomas and certificates of membership which he has received from learned societies at home and abroad. There are no less than eighty or ninety of these diplomas displayed, among them some of the most illustrious distinctions, such as that of Foreign Associate of the Institute of France, to which it is possible for any scientific man to attain, a striking testimony of the universal appreciation which Lord Kelvin's work has received wherever science is cultivated or learning flourishes. The Anglo-American Cable Co., the Eastern Telegraph Co., and the Brazilian Submarine Cable Co. sent addresses of congratulation, and exhibited instruments and objects of interest as illustrating the all-important share which Lord Kelvin's discoveries, his personal services, and inventions have had in the development of ocean telegraphy. Instruments in these exhibits were during the conversazione in communication with all parts of the world, and were employed in receiving addresses of congratulation. A warm letter of congratulation was sent by the Prince of Wales, and addresses were presented by representatives of the principal universities, learned societies, and other institutions throughout the world. All the universities and almost every college in the United Kingdom and Ireland sent delegates and addresses. The addresses were publicly presented to Lord Kelvin, and Lord Kelvin himself and several of the most distinguished foreign delegates received honorary degrees at a congregation of the University specially held in the Bute Hall on Tuesday for these purposes.

A grand banquet, to which the delegates and other distinguished guests were invited by the Corporation of Glasgow, was held on Tuesday evening in the St. Andrews Hall, and at the opening of the banquet the Lord Provost read a gracious message of congratulation received from the Queen. The celebration closed by a special excursion on the Firth of Clyde, up Loch Long and round the Island of Bute, given by the University authorities.

New Buildings of the University of Glasgow. Gable of Lord Kelvin's House on extreme left. Natural Philosophical Class-room Window over Western Gateway. Physical Laboratory to right of Western Gateway.

This brief summary of the events of the celebration we hope to replace next week by a fuller account of what has been undoubtedly one of the most unanimous and enthusiastic tributes of admiration which it has ever fallen to the lot of a scientific worker to receive. That such admiration for the achievements and the personal qualities of even the most illustrious man of science has been forthcoming in no unstinted measure, is a happy augury that peace may still have its triumphs, and good work done receive its due meed of reward.

A. GRAY.

THE APPROACHING TOTAL ECLIPSE OF THE SUN.

SINCE our last note on this subject, H.M.S. *Volage*, with the instruments belonging to Mr. Norman Lockyer's party which is to observe, if possible, on the south side of the Varanger fiord, has been detached from the Training Squadron to repair a slight damage. It is expected that she will be able to leave the Portsmouth Dockyard in a few days' time, and no alterations will be made in the arrangements already published.

The accompanying map (Fig. 1) shows the possible stations south of the fiord, with the duration of totality at each.

FIG. 1.—Duration of Totality South of the Varanger Fiord.

FIG. 2.—Stars and Planets near the Sun at the Time of Totality.

It has been announced that all the ships of the Training Squadron will proceed to the neighbourhood of the Varanger fiord to observe the eclipse.

Owing to the offer of Sir George Baden-Powell to take an observing party to Novaya Zemlya in his yacht, it is quite possible that that station may be occupied by English observers as well as by the expeditions sent by the St. Petersburg Academy of Sciences and the Kasan Society of Naturalists.

An expedition from Harvard College Observatory will accompany Prof. Todd to Japan, with the special object of obtaining photographs of the progress of the eclipse with a large prismatic camera.

Mr. Crommelin has communicated to the *Journal* of the British Astronomical Association a reduced map of

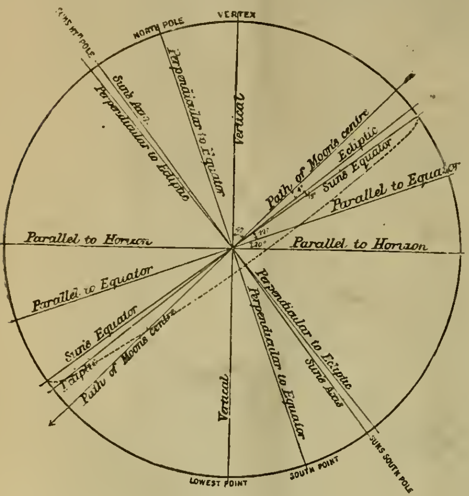

FIG. 3.—Conditions of Eclipse.

the stars and planets near the sun at the time of totality (Fig. 2), and a diagram showing the relation of the sun's axis and equator, and the path of the moon's centre to the horizon at Vadsö (Fig. 3). These, by the courtesy of Mr. Crommelin, we are enabled to reproduce.

According to Prof. Mohn, the weather chances in Lapland are vastly superior to those in Japan. We are glad also to learn that many lovers of nature are taking advantage of the opportunity of seeing one of the grandest of natural phenomena under the favourable conditions afforded by modern travel, not forgetting that the eclipse takes place in a region of beautiful scenery and in the holiday season of the year.

THE ELECTRICAL RESISTANCE OF ALLOYS.

THE recent researches of Profs. Dewar and Fleming upon the electrical resistance of metals at low temperatures have brought into strong relief the difference between the behaviour of pure metals and of alloys. In the former case the resistance shows every sign of tending to disappear altogether as the absolute zero of temperature is approached, but in the case of alloys this condition of things is widely departed from, even when the admixture consists only of a slight impurity.

Some years ago it occurred to me that the apparent resistance of an alloy might be partly made up of thermo-electric effects, and as a rough illustration I calculated the case of a conductor composed of two metals arranged in alternate laminæ perpendicular to the direction of the current. Although a good many difficulties remain untouched, I think that the calculation may perhaps suggest something to those engaged upon the subject. At any rate it affords *à priori* ground for the supposition that an important distinction may exist between the resistances of pure and alloyed metals.

The general character of the effect is easily explained. According to the discovery of Peltier, when an electric current flows from one metal to another there is development or absorption of heat at the junction. The temperature disturbance thus arising increases until the conduction of heat through the laminæ balances the Peltier effects at the junctions, and it gives rise to a thermo-electromotive force opposing the passage of the current. Inasmuch as the difference of temperature at the alternate junctions is itself proportional to the current, so is also the reverse electromotive force thereby called into play. Now a reverse electromotive force proportional to current is indistinguishable experimentally from a *resistance;* so that the combination of laminated conductors exhibits a false resistance, having (so far as is known) nothing in common with the real resistance of the metals.

If e be the thermo-electric force of the couple for one degree difference of temperature of the junctions; t, t' the actual temperatures; then the electromotive force for one couple is $e(t-t')$. If we suppose that there are n similar couples per unit of length perpendicular to the lamination, the whole reverse electromotive force per unit of length is $ne(t-t')$. Again, if C be the current corresponding to unit of cross-section, the development of heat per second at each alternate junction is per unit of area $273 \times e \times C$, the actual temperature being in the neighbourhood of zero Cent. This is measured in ergs, and is to be equated to the heat conducted per second towards the cold junctions on the two sides. If k, k' be the conductivities for heat of the two metals, l and l' the corresponding thicknesses, the heat conducted per second is

$$(t-t')\{k/l + k'/l'\};$$

or if $l/(l+l') = p$, $l'/(l+l') = q$, $l+l' = 1/n$, the conducted heat is

$$n(t-t')\{k/p + k'/q\}.$$

In this expression $p+q=1$, the symbols p and q denoting the proportional amounts by volume in which the two metals are associated. Thus when a stationary state is reached,

$$273 \times e \times C = n(t-t')\{k/p + k'/q\}.$$

This determines $(t-t')$ when C is given; and the whole back electromotive force per unit of thickness is rC, where

$$r = \frac{273 \times e^2}{k/p + k'/q}.$$

This is the expression for the false resistance per unit of thickness, which, it should specially be noted, is independent of n, the number of couples. The number of couples which co-operate is indeed increased by finer lamination, but the efficiency of each is decreased in the same proportion by the readier conduction of heat between the junctions. It is scarcely necessary to point out that the false resistance is called into play only by currents which flow *across* the laminæ.

In my original calculation the metals chosen for illustration were iron and copper. In this case (Everett's C.G.S. system of units, p. 192) $e = 1600$. The conductivities are to be measured in ergs. For iron, $k = \cdot164 \times 4\cdot2 \times 10^7$; for copper, $k' = 1\cdot11 \times 4\cdot2 \times 10^7$. Thus, if the metals are in equal volumes ($p = q = \frac{1}{2}$),

$$r = \frac{2 \times 273 \times 1600^2}{4\cdot2 \times 10^7 \times 1\cdot27} = 26\cdot2.$$

This is the thermo-electric addition to the true specific resistance, and is about $1\frac{1}{2}$ per cent. of that of copper. Such an addition may seem small; but it should be re-

membered that for the more distinctively thermo-electric metals e is much larger, and that it enters by its square. In any case it seems desirable that this complication should be borne in mind. The consequences which follow from recognised laws for laminated structures, however fine, must surely have some bearing upon the properties of alloys, although in this case the fineness is molecular.

RAYLEIGH.

NOTES.

THE De Morgan Memorial Medal has been awarded this year by the Council of the London Mathematical Society to Mr. Samuel Roberts, F.R.S. The medal is awarded every three years. Mr. Roberts was one of the earliest members of the Mathematical Society, and his first mathematical papers were contributed to the Society over fifty years ago. Since then he has continued, in the intervals of a busy professional career, to interest himself in the study of higher mathematics, and has published numerous papers, many of them of great value. The presentation of the medal will be made at the annual meeting of the Society in November next.

THE Council of the Society of Arts are prepared to award, under the terms of the Benjamin Shaw Trust, a gold medal, or a prize of £20. The medal, under the conditions laid down by the testator, is to be given "for any discovery, invention, or newly-devised method for obviating or materially diminishing any risk to life, limb, or health, incidental to any industrial occupation, and not previously capable of being so obviated or diminished by any known and practically available means." Intending competitors should send in descriptions of their inventions not later than December 31, 1896, to the Secretary of the Society of Arts, Adelphi, London, W.C.

ON Thursday last, a preliminary meeting was held in the Board Room of the Museums, William Brown Street, Liverpool, for the purpose of taking steps for the establishment in that city of a Zoological Garden on a scientific basis, and on the model of that in Regent's Park, London. On the motion of Prof. Herdman, seconded by Dr. Forbes, the following resolution was unanimously adopted:—"That in the opinion of this meeting it is desirable, in the interests of science and education in this city, to establish Zoological Gardens, containing a collection of living animals, and that those present form a Committee, with power to add to their number, for the purpose of advancing this object." The question of a site was considered, and it appeared that there was just now a favourable opportunity of securing land in a central position very suitable for the purpose. It was resolved that the following gentlemen be asked to form a sub-Committee to inquire fully into the matter, and prepare a report:—Prof. Herdman, Dr. Forbes, Messrs. A. L. Jones, A. A. Paton, A. S. Hannay, W. H. Picton, W. E. Willink, F. J. Leslie, and F. Radcliffe.

PRESIDENT CLEVELAND has appointed a scientific commission to investigate the condition of the fur seals in the North Pacific and Behring Sea. The members of the Commission are Mr. Jordan, of Stamford University (President), Lieutenant-Commander Moser, commanding the Fish Commission steamer *Albatross*, Dr. Stejneger and Mr. Lucas, both of the U.S. National Museum, and Mr. Townsend, Fish Commissioner.

THE recent electrical exposition in New York City proved so successful, pecuniarily as well as otherwise, that the managers have decided to establish a permanent exhibition. A revised estimate of the distances covered by the long-distance telegraphing at the exhibition on May 16, is 42,000 miles for the message to Tōkiō and back, covered in 47½ minutes, and over 15,000 miles for the double crossing of the North American continent and the Atlantic ocean, covered in four minutes.

THE Division of Forestry of the United States Department of Agriculture calculates the annual loss by fire to the forests in the States to amount to twenty-five million dollars.

AMONG the subjects of prizes for essays offered by the Royal Academy of Sciences of Denmark are:—Morphological and physiological researches on the asci of the Ascomycetes; the Danish species of Nematoids and Anguillulinæ; and the life-history of those Sphæriaceæ which are destructive to cereal crops.

IN the *Berichte* of the German Botanical Society, Herr A. Schober gives the result of some experiments on the effect of the Röntgen rays on the germination of the oat. He concludes that they differ from ordinary light rays in having no power of producing heliotropic curvatures, even in organs so sensitive to light as the axis of a growing seedling.

DR. Q. MAJORANA and Dr. A. Sella continue their researches on the effect of Röntgen rays and ultra-violet light on the discharge of electric sparks in air. In their latest communication to the Reale Accademia dei Lincei, they consider the manner in which the nature of the discharge is affected both by the action of these rays and by varying the sparking distance. Their present contribution includes a figure and description of the apparatus illustrated in their recent letter to NATURE, as well as of another arrangement by which the phenomena are well shown.

THE July number of the *Leisure Hour* is to contain a series of portraits of the Presidents of the Royal Society from its foundation, in 1662, to the present day. The portraits, thirty-four in number, occupy six pages of royal octavo, and form, so far as we know, an unique series. Of the thirty-six Presidents, two only—James West and Sir Cyril Wyche, neither of them very eminent men from a scientific point of view—are wanting. The accompanying article, on the Presidents of the Royal Society, has been been written by Mr. Herbert Rix, late Assistant Secretary to the Society.

THE earth-tremors and sounds produced by the Niagara Falls have been often referred to, in most cases probably with some exaggeration as regards their intensity. In a paper published in the *Yale Scientific Monthly* for last May, Mr. W. H. Brewer describes some careful observations made at various times during the last forty-five years. During one year spent at Lancaster, a village twenty-seven miles from the Falls, sounds, possibly due to the Falls, were heard on three occasions, but it was uncertain whether they might not have come from Buffalo, which is hardly ten miles distant. The tremor observations were made within a few miles of the Falls, and show that the vibrations are extremely irregular, varying both in amplitude and period. Sometimes they stop for an instant, then steadily increase in intensity, reaching one or several maxima, afterwards steadily declining. The momentary pauses do not, however, recur at regular intervals.

THE *Board of Trade Journal* reports that the Pharmaceutical Society of Prague will celebrate its twenty-fifth anniversary this year by an international exhibition of pharmacy, to be held from August 15 to September 15, at Prague, and to include the following groups:—Scientific apparatus and articles used in pharmaceutical work, and the literature having reference to same; machinery and various apparatus serving for the manufacture of pharmaceutical articles, pharmacy fittings, &c.; products and drugs used in pharmacy; manuscript books, statistics, and tables concerning the historical development of pharmacy; hygiene, and the care of invalids. There has been

no important exhibition of pharmacy in Europe since 1883, and the forthcoming one at Prague this year is to include all features of progress in the pharmaceutical branch and its ramifications. Meetings of various pharmaceutical societies will be held at Prague during the exhibition. Particulars may be obtained from Dr. Charles Fragner, Pharmacien, Président du Comité Exécutif, à Prague.

IN connection with the cloud observations to be made during the international cloud year commencing May 1, *Science* of May 29 has some interesting notes by Mr. R. De C. Ward, of the Harvard University, on scientific kite-flying under the superintendence of the Washington Weather Bureau, and the Blue Hill Observatory. Instead of being flat and tapering at the lower end, the kites used are box-shaped, with their ends open and their sides partly covered with cloth or silk, and when fine piano wire is used, instead of twine, they are found to be splendid flyers. Recent ascents have reached altitudes of nearly a mile above sea-level, and excellent results have been obtained by means of a self-recording instrument made by Mr. Fergusson, of the Blue Hill Observatory, which gives automatic readings of temperature, pressure, humidity, and wind velocity. Among the most important matters that have hitherto been noted is the presence of cold waves and warm waves at considerable elevations some hours before the temperature changes are noted at the earth's surface. The prospect of improving weather forecasts by such means and by the use of small pilot balloons, which can be made at slight expense, and can reach considerable altitudes, is considered to be very encouraging.

IN a paper in the *Photographische Mitteilungen*, Jahrgang 33, Hefte 1 and 2, entitled "Über chromatische Homofocallinsen und über meine chromatische Planparallelplatte," Dr. Hugo Schroeder gives an account of the uses that may be made of a compound lens of which the external surfaces are plane and parallel, while the component lenses join internally at surfaces of any convenient curvature. The simplest form of a double lens of this kind may be derived from an ordinary plano-convex achromatic objective by grinding the front (convex) surface of the crown lens to a plane. Such a lens would evidently have almost exactly the same chromatic and spherical aberrations as the removed plano-convex portion, but with the opposite signs. By substituting crown glass for flint, and *vice versa*, the character of the lens may be reversed. Inserted in the cone of rays coming from an achromatic object-glass, a suitable plane lens of this kind shows what would be the effect of altering the curvatures of the surfaces of the object-glass. For this kind of lens Dr. Schroeder proposes the name of "Corrector." Again, by the use of such a corrector an ordinary achromatic telescope may be fitted for photographic work, and this can be done without greatly changing the place of the focal plane. By moving the corrector along the axis, different groups of rays may be brought together to suit the photographic method employed. As independently pointed out by Prof. Keeler and Mr. Newall, one difficulty, however, cannot be overcome: the available field of view will always be very restricted; unless, indeed, the correcting lens is made so large as to become practically an extra member of the object-glass.

FROM an artesian well, 188 feet deep, recently bored at San Marcos, Texas, there were expelled more than a dozen specimens of a remarkable batrachian, together with numerous crustaceans. The latter are described by Mr. Benedict, and the batrachian by Dr. Stejneger (*Proc. U. S. Natl. Mus.*, vol. xvii., 1896). From the *American Naturalist*, it appears that the crustaceans comprise numerous shrimps (one new species, *Palæmonetes antrorum*), a lesser number of Isopods of a new genus (Cirolanides), and a very few Amphipods. All the species are white, blind, and have unusually long, slender feet and antennæ. The batrachian, for which Stejneger creates a new genus, is described under the name *Typhlomolge rathbuni*. It belongs to the family Proteidæ, and is more nearly allied to Necturus than to Proteus. Like the crustaceans, it is blind. The most remarkable external feature is the length and slenderness of the legs. In commenting on this peculiarity, Dr. Stejneger says: "Viewed in connection with the well-developed finned swimming tail, it can be safely assumed that these extraordinarily slender and elongated legs are not used for locomotion, and the conviction is irresistible that in the inky darkness of the subterranean waters they serve as feelers, their development being thus parallel to the excessive elongation of the antennæ of the crustaceans." The gills are external, its colour nearly white, having the upper surfaces densely sprinkled with minute pale grey dots, and its total length measures 102 mm.

YET another method or the separate identification of the colon from the typhoid bacillus has been furnished to the bewildered bacteriologist by Dr. Piorkowski from Berlin. Recognising the fact, now established by so many investigators, that both the colon and typhoid bacillus are frequently found in urine, and that the former is regarded as undoubtedly intimately associated with various processes of inflammation, Dr. Piorkowski has compared the growth of these two micro-organisms in broth, gelatine, and agar, to which he made additions of urine. He states that whereas the typhoid-bacillus cultures, both in colonies and tubes, exhibited fine hairy extensions resembling in the case of the colonies the well-known medusa-head-like appearance so characteristic of the anthrax bacillus, the colon bacillus never forsook its compact form of growth, and only occasionally were very small, short hairy extensions visible in the contour of the colonies. We agree with Dr. Piorkowski that his method of diagnosis is easily applied, but we are not altogether convinced as to its efficacy. Colonies of the colon bacillus may also exhibit very characteristic whip-like extensions under circumstances which at present we are not in a position to exactly determine, but these so-called abnormal colonies were obtained from colon bacilli derived from a sample of cystitis-urine. Already the catalogue of comparative tests is considerable through which typhoid and colon bacilli are required to be passed, and unless a decided advance can be recorded on these, we think it is unnecessary that the bacteriologist should add to his burdens by adopting any more.

THE artesian water question continues to largely occupy the attention of Australian geologists and engineers. We have received an abstract of Mr. J. P. Thomson's presidential address to the Royal Geographical Society of Australasia, on the alleged leakage of artesian water. The address seems to have been called for by the too ready acceptance by local writers of Mr. R. L. Jack's tentative suggestion that the artesian water of the porous Lower Cretaceous beds might largely leak away to the sea. Mr. Thomson considers there is no evidence of such leakage: it is true that at various places off the coast fresh water is known to rise through the sea-water from below, but there is no evidence to associate such submarine springs with Lower Cretaceous outcrops—the water may more probably be derived from the Tertiary beds which form the actual coast. On the other hand, the geological structure of the continent seems to prevent the possibility of an unbroken flow of water to a submarine outcrop, if such outcrop exists. Referring to the asserted great excess of the rainfall over the river-flow, which had been put forward as evidence of the artesian leakage, he points out on the one hand the enormous evaporation in such a climate as that of Central Australia (quoting some striking instances of this), and on the other hand, that there has hitherto been no systematic gauging of the flow of the Australian rivers.

PROF. J. S. BASSETT, in his "Slavery and Servitude in the Colony of North Carolina" (*Johns Hopkins Univ. Studies in Hist. and Polit. Sci. Studies*, 14th ser., iv.-v.), has recently published a valuable study on the history and sociology of slavery in North Carolina. In the West Indies the Spaniards early destroyed the native population, and so they imported the negro, and established colonies of slaves, driving them to the fields and back to the barracks, and treating them much as the Romans did their slaves. The ideal of the Virginian planter was that of an English county gentleman: he wanted to group his slaves around him, and deal personally with them. There were, however, two main obstacles: (1) the Indians must be either exterminated or driven into the interior, for fear of massacres; (2) the white population must become dense enough to resist any insurrection among the negroes, hence large numbers were not introduced at first. About 1712, these obstacles were practically removed. The first slaves in America were Indians; but as they were fierce and caused trouble, they were never very numerous. The first labourers the English took to the New World colonies were whites; these consisted of indented servants, transported felons, and kidnapped persons, usually children. From 1661-1671 the conscience of the English public was awakened, so that only properly registered emigrant servants could be taken across the Atlantic; besides, negro slaves were found to be cheaper than white servants. It was the survival of the fittest. Both Indian slavery and white servitude were to go down before the black man's superior endurance, docility, and labour capacity.

DR. BASSETT'S account of the social conditions of the natives is also interesting; nor is the history of the attitude of religion to the slave question less so. At first, at all events, the planters were unwilling to allow the conversion of negroes, there being a doubt in their minds whether conversion would not enfranchise them. When the negroes happened to be professed Christians they might join any church they liked, but till 1741 they were not allowed to have a church organisation or building among themselves. With the exception of the Society of Friends, who became unanimous on this point in 1776, none of the sects opposed the ownership of slaves.

A TRANSLATION of Dr. Carl Freiherr v. Tubeuf's "Diseases of Plants due to Cryptogamic Parasites," by Dr. W. G. Smith, is about to be published by Messrs. Longmans.

DR. J. DOERFLER, of Vienna, has published his *Botaniker Adressbuch*, a guide to botanists throughout the world. It contains upwards of 6000 addresses of botanists, as well as those of botanical gardens, botanical institutes, societies, and journals.

WE have received vol. iii., No. 4, of the "Bulletin from the Laboratories of Natural History of the State University of Iowa," containing several papers on the fauna and flora of Iowa, as well as of Mexico, Arizona, and Nicaragua. The *Botanical Gazette* has long been urging American naturalists to compile their local faunæ and floræ on some more satisfactory lines than the often very arbitrary division-lines between the States.

M. J. DAVEAU describes, in the *Journal de Botanique*, a remarkable example of proterandry extending over a whole season, in the case of a palm (species not given) belonging to the genus *Kentia* (*Howea*) grown in the open air in the Botanic Garden at Lisbon. The flowers are grouped together in clusters within the spathe, each cluster consisting of three flowers, two male and one female. The female flower in each cluster is only in a very rudimentary condition, even after the male flowers have shed their pollen and dropped; they remain in this condition through the autumn and winter, and expand only at the same period in the next summer, when the male flowers in other newly-formed inflorescences are discharging their pollen.

SCIENTIFIC book-hunters will be glad to have their attention called to two lists just issued. One comes from Messrs. Macmillan and Bowes, Cambridge, and contains the titles of more than seventeen hundred books and papers on pure and applied mathematics, astronomy, meteorology, chemistry, and other branches of physical science, from the libraries of the late Prof. Henry Smith and Mr. Cowper Ranyard; the other contains the titles of 341 works on branches of natural science, offered for sale by Messrs. Williams and Norgate.

MESSRS. J. B. LIPPINCOTT CO. have published a second edition of "A Manual of North American Birds" by Mr. Robert Ridgway. The work now runs into 653 pages, and is illustrated by 464 outline drawings of the generic characters. The knowledge of North American birds gained since the publication of the work in 1887, has been fully utilised in the preparation of the new edition; and the new species and sub-species added since that date are given in an appendix. Ornithologists, and particularly those in the United States, will be glad to have this carefully revised edition of a valuable manual.

OBSERVATIONS of local meteorology carried on in a systematic way, as they are in the Observatory of the Southport Town Council, furnish data of more than local value. The report of Mr. Joseph Baxendell, Meteorologist to the Corporation, upon the results of observations made in 1895 at places within and around the borough of Southport, has just been received, and it testifies to a large amount of careful work. In the course of his introductory remarks, Mr. Baxendell refers to "the serious differences between the indications of the Campbell-Stokes Standard and the Jordan Photographic Sunshine Recorders." It is hardly satisfactory that the duration of sunshine should be recorded so differently by the two classes of instruments.

THE Royal Cornwall Polytechnic Society has published its sixty-third annual report, being for the year 1895. For many years the Falmouth Observatory, in connection with that Society, has been one of the principal stations of the Meteorological Council, and in addition to the records of the photographic and other self-recording instruments required by that body, it publishes results of magnetic and sea temperature observations. During the year in question, Prof. Rücker spent some time at the observatory for the purpose of comparing the magnetic instruments with those at Kew, and his report bears testimony to the skill and accuracy of the observer, and to the thoroughness of the work done. The Society holds an annual exhibition, when any special features are introduced by which industry may be encouraged, and visitors interested and instructed. The report contains accounts of interesting lectures on the old Falmouth Packet Service, by Mr A. H. Norway, and on some senses in fishes, by Mr. M. Dunn

UNDER the title "Lloyd's Natural History," Messrs. Edward Lloyd (Limited) is issuing in parts the works which Messrs. W. H. Allen and Co. have for the past two or three years been publishing as "Allen's Naturalist's Library," and which is itself a revised and enlarged edition of "Jardine's Naturalist's Library." The first part of this *réchauffé* series has just been received, and we may be pardoned a little surprise at finding that no reference is made in it to the original edition, so that to the general public "Lloyd's Natural History" appears as a new work. The present part comprises 112 pages and eleven coloured plates, and is a section of one of the volumes on "British Birds" contributed by Dr. Bowdler Sharpe to "Allen's Naturalist's Library." We are glad to see the issue of this series in parts, notwithstanding the information withheld as to the origin of it. In spite of the many unsatisfactory figures, the work is sound and methodical, and its serial publication wil undoubtedly increase the number of students of natural history.

SEVERAL parts of the very fine "Illustrations of the Zoology of H.M. Indian Marine Surveying Steamer *Investigator*," under the Commander, A. Carpenter, the late Commander, R. F. Hoskyn, and Commander C. F. Oldham, have lately been received. The plates are splendid examples of photo-etchings, and they will be treasured by marine zoologists. Fishes are represented upon sixteen plates, Crustacea upon fifteen plates, and Echinoderma upon five plates. The illustrations are only accompanied by brief explanations, the descriptions of the various species having appeared in the *Annals and Magazine of Natural History*, and in the *Journal of the Asiatic Society of Bengal*. Mr. A. Alcock is responsible for the fishes described and figured, and, in conjunction with Mr. A. R. S. Anderson, for the Echinoderma. The Crustacea have been mostly done under the direction of the late Mr. J. Wood-Mason.

NEARLY a year ago (NATURE, vol. lii. p. 290), the second volume of the second edition of Dr. George Lunge's treatise on "The Manufacture of Sulphuric Acid and Alkali" (Gurney and Jackson) was reviewed in these columns, and the value of the work to investigators and industrial chemists as a standard work of reference on alkali manufacture was pointed out. The third volume, completing the second edition of the book, has now been published, and the words of praise applied to the second volume are just as fully deserved by the present one. The amplification of the original text has been so considerable, and the revision so thorough, that the work has grown beyond recognition. Only a few chapters resemble those of the first edition, and the chapters on ammonia-soda, on the more recent soda-process, on the Deacon process, and the other chlorine processes, have been entirely rewritten; while a section on the preparation of alkalis, chlorine, and chlorates by electrolysis, appears for the first time. The second edition of the complete work is half as large again as the first; it is well up to date, and forms a most serviceable survey and digest of the whole ground of alkali manufacture.

THE meteorological and magnetic observatory of the University of Odessa has for its functions not only the reading of the numerous instruments with which it is equipped, and the discussion of the results observed and registered, but it is intended also to serve as a high school where students of the faculty of physics and mathematics can be trained in the work of meteorology and physical geography. In order to give more importance to this course, Prof. Klossovsky has drawn up a syllabus, which is printed in the 1895 volume of the "Annales" of the Observatory at Odessa. The course is divided into three parts, the first two of which are devoted to fundamental observations, to the installation and study of instruments used in meteorology and terrestrial physics, and to the determination of various elements. The third course is intended for those who propose to take up physical geography or meteorology as a special subject. The programme is an admirable outline of the work of meteorology and terrestrial physics, and but for limit of space we would give a full translation of it. Schools in meteorology are so few, that the development of the curriculum of the Imperial University at Odessa will be welcomed by all who think that trained investigators and experimental work are needed for the advancement of the science.

THE additions to the Zoological Society's Gardens during the past week include a Hoolock Gibbon (*Hylobates hoolock*, ♀) from Assam, presented by Mrs. Firman; two Fat Dormice (*Myoxus glis*) from Austria, presented by Mr. John G. Haggard; a Short-toed Eagle (*Circætus gallicus*) from Egypt, presented by Dixon Bey; a Vulturine Eagle (*Aquila verreauxi*) from South Africa, presented by Mr. J. Clark; two Short-eared Owls (*Asio brachyotus*) from Ireland, presented by Captain R. A. Ogilby; five Cormorants (*Phalacrocorax carbo*) from the Isle of Mull, presented by Maclaine of Lochbuie; three Dwarf Chameleons (*Chamæleon pumilus*) from South Africa, presented by Miss Jessie M. Hudson; eight Natterjack Toads (*Bufo calamita*), two Common Toads (*Bufo vulgaris*), British, presented by Mr. Stanley S. Flower; two Axolotls (*Siredon mexicanus*) from Mexico, presented by Mr. W. Temple; nine Green Turtles (*Chelone viridis*) from Ascension, presented by Mr. J. C. Adlam; a Hoolock Gibbon (*Hylobates hoolock*, ♀) from Assam, an Indian Chevrotain (*Tragulus meminna*), two Indian Drongos (*Chibia hottentota*), two Tigers (*Felis tigris*, ♂ ♀) from India, a Javan Chevrotain (*Tragulus javanica*) from Java, a Harnessed Antelope (*Tragelaphus scriptus*, ♂) from West Africa, deposited.

OUR ASTRONOMICAL COLUMN.

PHOTOGRAPHS OF STELLAR SPECTRA.—Dr. F. McClean is now engaged on a photographic investigation of the spectra of the northern stars down to the third magnitude. About 160 stars will thus be included in the survey. Some of the results, which have been recently communicated to the Royal Astronomical Society, comprise the spectra of twenty-three characteristic helium stars, and photographs of the spectra of six stars of the third magnitude showing the transitions from one type to another (*Monthly Notices*, vol. lvi. p. 428). The instrument used is a photographic telescope of 12 inches aperture and 11 feet 3 inches focal length, having an objective prism of the same aperture placed in front of the object-glass. The refracting angle of the prism is 20°. The prism is mounted on a hinged frame, and the cell containing it can be rotated within the frame, so that all necessary adjustments can be effected with facility.

THE NATAL OBSERVATORY.—Two reports which have recently been received from Mr. Nevill, the Superintendent of the Natal Observatory, indicate considerable astronomical activity at this southern station. "The principal series of observations in progress is the comparison of the declination deduced from observations made at the observatories in the northern and southern hemispheres by a comparison by Talcott's method of the zenith distance of northern zenith stars and southern circumpolar stars at upper and lower culminations." Over a hundred pairs of stars are under observation. The publication of the Greenwich observations of Mars during the opposition of 1892 renders it possible to utilise the corresponding Natal observations for the determination of a new value of the solar parallax, and this work will be undertaken. During the opposition of Mars in 1894 the weather proved very unfavourable, and no observations of value were secured. A great mass of important work done at the observatory awaits facilities for publication. The entire staff amounts to only four observers and computers, and the instrumental equipment is equally small. The system of time signals and meteorological work were carried on as in former years.

POSSIBLE CHANGES IN THE EARTH'S ROTATION.—As the result of a recent investigation (*Comptes rendus*, June 1), Prof. Newcomb makes the startling suggestion that the earth's rotation is not perfectly uniform. The discussion was undertaken in connection with the long-period inequalities in the moon's mean motion, which so far have not been satisfactorily explained. The possibility of a variation in the earth's rotation period being admitted, and consequently of an error in our mode of reckoning time, it becomes necessary to employ some method of measuring time which shall be independent of the earth's rotation. This appears to be best furnished by observations of the transit of Mercury. Prof. Newcomb has accordingly discussed all the November transits since 1677, and has compared the observed times of ingress and egress with those computed on the basis of his new tables for the sun and Mercury. Although in many cases the residuals may not be greater than the probable errors, there is a significant systematic character about them, as shown when the observations are grouped as follows:—

Transits.	Residuals. s. s.
1677—1769	-5.4 ± 2.5
1789—1861	$+6.4 \pm 1.5$
1868	-1.5 ± 3.5
1881—1894	-3.1 ± 1.6

It is concluded that "the observations of transits of Mercury clearly indicate small variations in the rotation of the earth, of

which the integral amount, during long periods of time, probably reaches five, or even ten seconds. In particular it seems that between 1769 and 1789 a retardation of the earth's rotation took place, and another between 1840 and 1861. Towards 1862 this slackening was followed suddenly by a well-marked acceleration, which possible persisted up to 1870."

It may be added that the supposed variation does not seem to account for the lunar inequalities to which reference has been made.

THE LADIES' CONVERSAZIONE OF THE ROYAL SOCIETY.

THE second of the two annual conversaziones of the Royal Society—the one to which both ladies and gentlemen are invited—was held in the rooms of the Society at Burlington House, on the evening of Wednesday in last week. As many of the scientific novelties exhibited were shown at the conversazione held in May, and have already been described in these columns (May 14), it is unnecessary to refer to them again. Only the new exhibits are therefore described in the present report.

In addition to Mr. Herbert Jackson's demonstration of the various degrees of phosphorescence of different subjects under the action of Röntgen rays, several other exhibits were devoted to methods used and results obtained with the rays. Prof. S. P. Thompson showed the production of electric dust-shadows by Röntgen rays. When the rays are allowed to fall upon an electrified sheet of aluminium placed above a plate of ebonite, they carry electric charges to the plate and electrify it. If objects of metal are laid on the ebonite sheet they intercept the Röntgen rays, and the part of the ebonite surface immediately shaded by them does not become electrified. On removing the ebonite plate and dusting upon it Lichtenberg's powders (mixed sulphur and red lead), the electric shadows become visible.

Prof. Thompson also showed a number of experiments on Röntgen's rays, viz.: (*a*) Cryptoscopic use of luminescent screens (revealing contents of packages, bones of hand, &c.) by employment of focus tube (Jackson's pattern); (*b*) discharge of electroscope by Röntgen rays; (*c*) new forms of X-ray tubes, including one for insertion in mouth; (*d*) apparatus of Ebert for producing luminescence by electric oscillations; (*e*) stereoscopic Röntgen-ray photograph of rabbit.

Electric discharges in vacuum was the subject of exhibits by Messrs. Siemens, Bros., and Co. The exhibits were (1) a facsimile of Dr. Wm. Watson's vacuum tube of 1751. This was the first apparatus ever constructed for experiments on the electric discharge in a vacuum. The discharge from a Leyden jar passed through ten inches, and that from a frictional machine through three feet, the whole length of the tube. (2) Facsimile of Lord Cavendish's double barometer of 1751, used by Dr. Wm. Watson in his researches. (3) Facsimile of Dr. Wm. Morgan's shortened barometer of 1785. Dr. Morgan, by long-continued boiling of the mercury in a barometer tube, produced a vacuum of such excellence that no discharge would pass, and equal, therefore, to that in a Hittorf or Crookes' tube of the present day. It is probable that it would have sufficed for the production of Röntgen rays. (4) Apparatus for showing electric discharges at different degrees of exhaustion from 70 mm. to 0 mm. (5) Photographs obtained by means of Röntgen rays, showing relative transparency of different kinds of wood, minerals, and glass.

A series of striking Röntgen photographs was shown by Dr. Macintyre. The marvellous advance made in Röntgen photography will be understood from the following statement of the subjects of Dr. Macintyre's pictures: (1) *Hard Structures.*—Life-sized photographs of different parts of the human skeleton, including the spine, ribs, shoulder, elbow and other joints of the body. Some of the negatives were 24 by 20 inches. (2) *Animal Kingdom.*—A series of the animal kingdom, such as the fish, frog, adder, &c. (3) *Soft Tissues of the Body in Health and Disease.*—Human heart in the living adult subject. The same in health and disease, also the tongue, tissues of the neck, including the larynx, &c. (4) *Instantaneous Photographs of Different Objects.*—The time of exposure was unknown, but the most rapid picture shown was taken with a single flash of the tube, due to one vibration of the interrupter of a ten-inch spark coil.

Mr. J. J. H. Teall exhibited a series of photographs of the electric discharge at various stages during the exhaustion of a Crookes' bulb of the Jackson type.

A small dynamo for measuring the permeability and hysteresis of iron was exhibited by Prof. W. E. Ayrton and Mr. T. Mather. The specimen to be tested, which may be in the form of a round bar or a bundle of thin plates, forms the yoke of the dynamo, and through a coil surrounding it is passed the magnetising current, the winding of this coil being so arranged that the current in amperes is numerically equal either to the magneto-motive force per centimetre of the bar, or to one-tenth of that value. When the armature is run at a speed of 1150 revolutions per minute, the induction per square centimetre in the bar is approximately equal to 10,000 times the E.M.F. in volts produced. Hence not merely the magnetising current but also the induction is measured by a *steady* deflection, and not, as is usual, by the *instantaneous* swing of a ballistic galvanometer. The magneto-motive force required for the air-gap and joints is determined experimentally by the use of a standard bar whose B H curve is accurately known.

Mr. J. Frith demonstrated the different effects produced by superimposing a small alternating current on a direct current arc according as cored carbons or solid carbons are employed. When a small alternating current is superimposed on a direct current arc formed with *cored* carbons, the oscillations of potential difference and current are in the *same* direction for all frequencies higher than about $1\frac{1}{2}$ periods per second. On the contrary, if the carbon be *solid*, the oscillations of potential difference and current are in the *opposite* direction for all frequencies tried up to 256 periods per second. This difference was exhibited by the visible motion of ammeter and voltmeter needles.

Microscopic internal flaws inducing fracture in steel axles, rails, and propeller shafts were shown by Mr. T. Andrews. This exhibit consisted of a series of accurate micrographs taken at a high magnifying power, illustrative of the microscopically visible and tangible micro-flaws, almost invariably present in considerable number, in steel railway axles, rails, tires, propeller shafts, &c. The presence of these germs of metallic disease in steel (mostly due to sulphur and other impurities) greatly influences the deterioration by fatigue of the metal, and they are a potent factor in inducing the sudden fracture of engineering constructions in steel.

Mr. J. Macfarlane Gray exhibited a multiplication frame. In this contrivance, for obtaining the product of two multidigital numbers, product cards, as on "Napier's rods," are set for one of them upon a sole frame, and sliders on a grid are shifted to set up the other. Each slider has a pane of plass at mid-length. The grid is fitted to the sole frame upon a pair of stepped guides, and is slid along over the cards one figure at a time. At each step the component products in one of the vertical columns of the common multiplication rule are exhibited at the panes and added mentally. In this way the final product is obtained without transcribing the intermediate products.

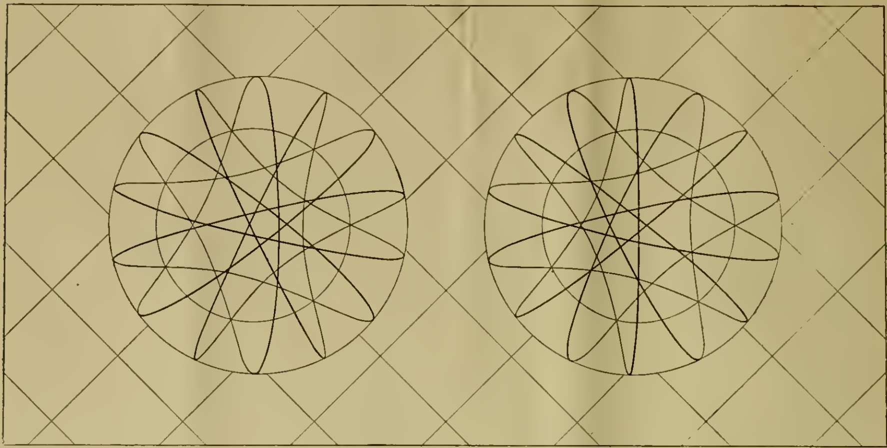
Exhibits illustrative of applications of the mathematical theory of frequency were shown by the Applied Mathematics Department of the University College, London. They included: (1) Diagram illustrating the relative variation of different organs in men and women of diverse races, by Miss Alice Lee, G. U. Yule, and K. Pearson. (2) Diagrams showing that 25 per cent. of the married population produce 50 per cent. of the next generation—Reproductive Selection, by K. Pearson. (3) Diagrams illustrating barometric frequency over the British Isles, by Miss Alice Lee, C. Jakeman, and K. Pearson. (4) Frequency recording barometer, by G. U. Yule and Cambridge Instrument Co. (5) Amplified integrator for finding mean, mean square and mean cubic deviations, and frequency skewness, by Amsler-Laffon. (6) Prof. Ranke's craniophor, used in comparing variation of skulls, as determined by English and German methods, by A. Martin-Leake and K. Pearson. (7) Skew binomial machine, by G. U. Yule. (8) Model of contour-tracer for finding areas of section of small objects.

Stereoscopic views of algebraic spherical catenaries and gyrostat curves were exhibited by Prof. A. G. Greenhill and Mr. T. I. Dewar. The mathematics of the spherical catenary are discussed in a paper by Prof. Greenhill in the volume of the *Proceedings of the London Mathematical Society* for the current year, and a diagram of a closed algebraical one with five

loops is there given. This was the first case in which it had been found possible to express the integral

$$\int \frac{Adz}{(1 - z^2)\sqrt{Z}}$$

algebraically, where $Z = (1 - z^2)(h - z)^2 - A^2$, and A and h are constants. The accompanying diagram is for the next possible case of seven loops, and has been made by Mr. T. I. Dewar. The circle in the lower hemisphere shows where the pressure of the chain on the sphere becomes zero; below that, the chain is supposed to rest on the interior of the hollow sphere. The tesselated pavement indicates the position of the *directrix-plane*. The tension at any point of the catenary is the same as in a chain hanging vertically to this plane, like a similar property in the plane catenary. A great many other cases with different numbers of loops have been examined, but the results turn out to be imaginary



Mr. Robert L. Mond exhibited the following apparatus intended for the Davy-Faraday Research Laboratory of the Royal Institution: (1) Kilogram automatic balance (Rueprecht, Vienna). (2) Prism automatic spectroscope (Kruss, Hamburg). (3) 1-inch spectrometer after Landolt and Brühl (Hildebrandt, Freiberg). (4) Hüfner photo-spectrometer (Albrecht, Tübingen). (5) Large polariscope 6-inch Landolt. (6) Small Landolt polariscope (Schmidt and Haensch). (7) Berthelot platinum bomb (Golaz, Paris). (8) Glass scale cathetometer (R. Fuess, Berlin). (9) Petrographical microscope (R. Fuess, Berlin). (10) Millivolt meter reading Centigrade degrees for Le Chatelier Thermophile (Keiser and Schmidt, Berlin). (11) Compensation box of Physikalische Reichsanstalt, Berlin (Wolff, Berlin). (12) Set of standard resistances (Wolff).

Prof. Dewar showed a portable apparatus for the production of liquid air and oxygen. A working model of support for large specula, designed to leave the line of collimation undisturbed, was exhibited by Dr G. Johnstone Stoney.

Mr. F. McClean exhibited (1) photographic stellar spectra of Type III., including spectra of *o* Cetus (showing bright lines Hγ and Hδ), α Taurus, α Orion, α Scorpio, β Andromeda, α Cetus, δ Ophiuchus, μ Gemini, δ Virgo, β Pegasus, α Hercules. (2) Photographic spectrum of Secchi's Type IV. This was a spectrum of the star 152 Schjellerup ($5\frac{1}{2}$ magnitude), compared with spectrum of α Orion. (3) Series of photographic spectra of the variable star β Lyra, compared with spectra of β Orion and δ Taurus.

A new form of stereoscope was shown by Sir David L. Salomons. This stereoscope has been designed to suit the vision of all persons, without straining the eyes. Many individuals who are unable to use the ordinary stereoscope have been able to obtain the solid effects with this instrument. The lenses may be angled, and moved to and from the centre at will. Also the distance can be varied between the picture and the lenses. The distance between picture and lenses is greater than usual, to allow a wider mirror, which is advantageous.

A number of cloud photographs taken in different parts of the ocean world were exhibited by Captain D. Wilson-Barker; and Mr. F. H. Worsley-Benison exhibited a series of seascape photographs. The photographs were enlargements in carbon. The whole picture in each subject was the result of one exposure only.

Coming now to natural science: Models of the flowers of *Aristolochia gigas* from Brazil, and of *Stapelia gigantea* from Natal (made by Miss Emett for the Museums of the Royal Gardens, Kew) were exhibited by the Director, Royal Gardens, Kew. Flowers with livid colouring and exhaling indol or some allied body occur in different families of the vegetable kingdom. Kerner ("Natural History of Plants," translated by F. Oliver, vol. ii. pp. 197–200) thus describes them: "Flowers provided with indoloid scents resemble animal corpses in their colouring, having usually livid spots, violet streaks and red-brown veins on a greenish or fawn-coloured background." "Such flowers . . . are always visited by carrion-flies or dung-bettles in abundance."

The Director of the Royal Gardens also showed photographs of Hæmatozoa of fly disease of South Africa (exhibited on behalf of the Government of Natal). For the last half-century the Tsetse-fly has been notorious as a terrible scourge to live-stock, and the most formidable of impediments to colonisation in Equatorial and South Africa. Surgeon-Major Bruce has now discovered that the fly is itself innocuous, and is only fatal to animals when it is the carrier of a flagellated infusorian (*hæmatozoon*) which it introduces into their blood.

Two coloured casts of the New Zealand lizard, Hatteria or Sphenodon, were exhibited by Prof. Ray Lankester. The casts were taken at the Zoological Society's Gardens from a full-grown specimen immediately after death, and painted by Prof. Lankester, so as to give the natural colours. Stuffed specimens of lizards' skins are very difficult to prepare with any approach to natural form and folding of the skin. Such casts as those shown are useful as preserving form and pose.

Mr. Frederick James exhibited examples of British Lepidoptera (*Rhopalocera*) denuded of scales to illustrate their neuration. In each specimen the scaleless left fore and hind wings illustrated the neuration of the genus.

An experiment to ascertain the period at which larvæ are sensitive to surrounding colours, formed the subject of an exhibit by Prof. Poulton. The larvæ of *Amphidasis betularia* were, after hatching, surrounded with green leaves and shoots. During

each of the stages of growth a batch of larvæ was removed and surrounded by dark twigs, and at the end of the stage restored to the green leaves. By comparing the colours of the mature larvæ in the different batches, it is possible to determine the period of larval susceptibility.

The following forms of variation in butterflies of the genus *Heliconius*, of Tropical America were exhibited by Mr. W. F. H. Blandford. (1) Variation in *Heliconius erato*, L. There are three main types with the basal patch of the hind-wings, respectively, red, blue, or green. The green form is dominant in Panama; it occurs throughout Central America, but not in South America, except sparingly in Colombia and Venezuela. At Sao Paulo, on the Upper Amazons, the blue form alone occurs, or the basal patches may be obsolete. (2) Variation in *Heliconius thelxiope*, Hübn., and *Heliconius vesta*, Cram. Both forms occur together, and are very variable in Cayenne and the Lower Amazon Valley. Further west definite parallel geographical races occur of both. *Heliconius thelxiope* is connected by intermediate forms in Cayenne with *Heliconius melpomene*, L., a widely distributed species, which occurs in the Amazon Valley at Santarem and Obydos only, and is not found in the humid forest. In Bolivia *Heliconius vesta* merges into *Heliconius phyllis*.

Mr. W. Saville Kent showed interesting photographs and specimens illustrating the natural history and ethnology of Australia. The Hon. Walter Rothschild exhibited a group of recently described and other rare Birds of Paradise and Bower-birds.

During the evening four lantern demonstrations were given in the meeting room of the Society. Prof. A. C. Haddon showed a series of slides illustrating the evolution of the cart, and another which illustrated the evolution of the Irish jaunting-car. The Altels avalanche, which occurred in September 1895, was described with photographs by Dr. Tempest Anderson, and Prof. Herkomer gave a demonstration of his new gravure process. Prof. Dewar dealt with liquid air, and showed the following experiments illustrative of low temperature effects:—Filtering liquid air; vacuum vessels boiling at 350° F. below the freezing point; colour and absorption spectra; spheroidal state; solid alcohol; frozen soap-bubble; distilling mercury and phosphorus; liquefaction and solidification of gases; fusible metal spring; brittle indiarubber and its expansion by cold; the diamond burning in liquid oxygen; magnetic oxygen; photographic action and phosphorescence; ignition by means of a lens of liquid air; cooling a vessel 380° F. below the freezing point, until the air of the room condenses on the surface to the liquid state.

The Lords of the Committee of Council on Education have arranged for the public exhibition, in the Western Galleries of the Science Museum at South Kensington, of a number of the objects shown at the soirée. The exhibition will remain open to the public for about a fortnight.

ON THE ROTATION OF THE EARTH.[1]

THE recent discovery of periodical variations of terrestrial latitudes demands a revision of the actual theory of the rotation of our planet. This theory, based upon the hypothesis of the absolute rigidity of the earth, admits of variations of this kind, but very different in their laws from those of the observations. The period of revolution of the terrestrial poles given by the theory is one of about ten months. That which the observations give us lasts nearly fourteen months. Still further, the attentive analysis of the observations of the latitudes, executed of late by Mr. Chandler, shows us that the movement of the terrestrial poles is compounded of two others, of which the periods are, the one of 430 days, and the other of twelve months.

Following the order of the ideas established in the science by the celebrated cosmogenic hypothesis of Laplace, we ought to attribute this disagreement of the theory and the observations to the interior fluidity of the earth. But the illustrious physicist, Lord Kelvin, does not admit that the fluid nucleus of the earth may be of considerable enough dimensions. The greatest part of the astronomers of our day adhere to this opinion. They refer the said discordance to the terrestrial globe being elastic.

[1] Abridged translation of a paper by Th. Sloudski, Professor at the University of Moscow (*Bulletin de la Société Impériale des Naturalistes de Moscou*. Année 1895, No. 2).

In considering the hypothesis of a thin rigid crust of the earth as contrary to all given physics, the celebrated English physicist affirms in his memoir "On the Rigidity of the Earth," *Phil. Trans.*, 1863, and in the first edition of the "Treatise on Natural Philosophy" (§§ 847 and 848), that this hypothesis is also incompatible with the observations of the precession and of the nutation. On subsequently withdrawing certain of these astronomical objections, he has replaced them by some others.

To be able to appeal to objections of this kind, the theory of the rotation of the earth considered fluid in its interior ought to have been previously established. Lord Kelvin has not done it. He has limited himself to enunciating in general terms the principal propositions of this theory. To be able to judge of the said objections of the celebrated English physicist, the theory in question must be previously established.

The problem of the rotation of the earth—supposed fluid in its interior—was approached by W. Hopkins in 1839 (*Phil. Trans.*, 1839-40-42); but the state in which hydrodynamics then was found, did not permit the English savant to treat the matter in a satisfactory manner. The more recent attempts to solve this difficult problem have not been more successful.

We shall endeavour in the present article to give a more perfect solution of this important problem. To render this task more easy, we shall assume that the nucleus of the earth is homogeneous, and of the form of a planetary ellipsoid.

The success of our task is assured by the beautiful researches of our clever geometrician, Prof. N. Joukovsky, relative to the movement of a solid body with cavities filled with an incompressible homogeneous fluid. We have only to apply these researches to our special problem. We hope to lessen the difficulties of this application by the supposition that the rotatory motion of the entire terrestrial mass differs very little from the uniform rotation. The proposition of the celebrated Laplace, relative to the effect of friction of the fluid parts of the earth upon its rotatory motion, affords us a solid foundation for the said supposition ("Œuvres Complétes de Laplace," tome v. p. 283).

We shall commence our article with an abridged exposition of the theory of the rotation of a solid body, which has a cavity filled with an incompressible homogeneous fluid. In the development of the principal formulæ of this theory we shall employ the most simple method, that of the illustrious Poisson. We shall equally profit by them in our transformations of the hydrodynamical equations.

(The final paragraphs, after thirty large octavo pages of intricate mathematics, are as follows.)

We have taken our problem with some considerable restrictions relative to the form, to the position, to the structure, and to the movement of the terrestrial nucleus. This renders almost useless the detailed comparison of our results with the given astronomical ones. We will only say some words relative to one of these results, of which the generality is indubitable.

The hypothesis of a fluid nucleus of the earth being admitted, and the exterior forces neglected, the movement of the terrestrial poles ought to be composed of two periodic movements. The period of the former of these movements is perhaps of twelve or fourteen months, that of the second ought to be pretty nearly a day.

The astronomical observations do not show us this second movement of the poles. Is not this a reason for taking exception to the hypothesis of the fluidity of the earth in its interior? By no means. It is in the first place possible that the smallness of the amplitude of the movement in question may make it unrecognisable. The smallness of the factors μ_2, ν_2, renders this supposition probable. Secondly, it may also be admitted that the want of the appropriate observations causes us to ignore for the present this movement, although its amplitude may be appreciable. One may also suppose that the period of the movement in question, from the usual order of astronomical observations, appears to us to be a period of twelve or of fourteen months. For instance, should the said period be equal to twenty-four sidereal hours exactly, and the observations of the latitude of any astronomical observatory be made every midnight during a good many years, the result of them will be the period of twelve months.

This last supposition appears to us worthy of attention, because according to our opinion the explanation of the period of twelve months by meteorological causes, as is adopted at present by some astronomers, wants probability.

THE ANKLE-JOINT IN MAN, AND THE INHERITANCE OF ACQUIRED CHARACTERS.

PROF. RETZIUS has lately published an account of certain observations on the fœtus of Swedes, which, in connection with similar observations recorded by Surgeon Havelock Charles on the Punjabite, he believes to support the Lamarckian view that acquired characters are inherited. He endeavours to show that the evidence in support of the theory is to be found in our own skeletons.

Some years ago, Prof. Arthur Thomson pointed out that in certain races of men who habitually adopt a "squatting position," the tibia and astragalus present additional articular facets, allowing greater flexure of these bones upon one another, than is possible (or at any rate normal) in Europeans and other civilised races who have given up squatting, and in which these facets are absent. Accompanying these facets there is a retroversion of the head of the tibia. Both these characters are present in apes and in certain prehistoric races, and Surgeon Havelock Charles described, a year or two back, a series of instances of their presence not only in the adult Punjabite, but in the fœtus. At the meeting of the British Association at Oxford, Prof. A. Macalister exhibited these specimens, as well as similar specimens taken from British infants, and a discussion followed on the meaning of these peculiarities. Now Retzius ("Ueber die Vererbung erworbener Eigenschaften," *Biol. Untersuch*, n.f. vii.) records these same characters in fœtal Swedes, from an early age, even up to eight months; and reviewing the facts, he comes to the conclusion—in which I think most of us would agree—that the presence of these characters, viz. the retroversion of the head of the tibia and "Thomson's facets" is a more primitive condition than their absence in normal Europeans of the present day; that they have been inherited from early times; and in those peoples which habitually adopt the "squatting" position they have become gradually further developed. This last conclusion is perhaps open to question: it is quite possible that even in these races they are less developed than in ancestral forms. But Retzius proceeds to contend that Europeans have undergone gradual change in their skeletons from generation to generation; they no longer sit on their haunches, and have gradually lost the power to do so, and as a consequence "Thomson's facets" have disappeared; and he concludes that "it is, therefore, we Europeans who, on account of changed habits, have undergone changes, and it is in us that these changes have gradually been inherited."

But here, it seems to me, that Darwinians would join issue with Retzius. His own and other observations show that the *changes* are not inherited; for the characters of the bones are inherited from the ancestral ape-like forms, and it is, surely, only on account of individual habit that the peculiarities are not present in the adult.

It is by no means clear what is the "acquired" character on which Retzius hangs his views. Is it the osteological peculiarity, or the habit of using chairs to sit upon, instead of employing the squatting posture? His own researches show that the osteological characters are *not* acquired, whilst the habit of walking upright and sitting on chairs is distinctly acquired, and it is in relation to this acquirement that the osteological peculiarities cease to be evident. Young children, as we know, can and do sit upon their haunches, and can move their legs and ankles in a way that an adult, unless he is fairly athletic, finds it impossible to do; and it appears probable that the disappearance of the facets in the adult is closely connected with the ossification of the bone, which will obliterate the facets now no longer brought into use. It would be interesting to examine in this connection the leg-bones of "contortionists" and others who make a free use of their legs and ankles, for a very little practice enables even civilised men to employ exaggerated movements of their limbs.

Another point to which attention might be directed (which indeed may have been looked into) is the character of the articulation of the bones of the great toe in those races which make use of this digit. A casual observation on the skeleton of an Andaman shows that the articular surface of the first metatarsal with the entocuneiform is distinctly more rounded than in a European; a feature in which there is an approach to the condition in the apes. It might have been presumed that some difference, similar to that in Europeans and Punjabites, would be found in digitigrade and plantigrade mammals; but the result of a brief examination of skeletons of such forms is sufficiently surprising to be referred to; for instance, in the lion there is a facet of the same kind as, but not really homologous with Thomson's facet, at the lower end of the tibia. This is absent in the bear and the dog; it is also absent in the sea-otter. It is present, however, in the beaver and other rodents; it exists in some ruminants, as well as in the horse, but is only slightly developed in the tapir, and is absent in the Suidæ.

THE PARIS OBSERVATORY.

M. TISSERAND'S report on the work accomplished in the Paris Observatory during 1895 has come to hand. The principal points referred to are indicated in the subjoined summary.

The revision of the right ascensions of the fundamental stars of the Paris Catalogue is completed, and the revision of the polar distances was commenced in May of last year.

During the year, MM. Henry obtained 319 plates for the photographic star catalogue, which number brings the total up to 1155. Eighty-eight plates, containing 35,814 stars, were measured under the direction of Mlle. Klumpke, and the measures of 13,663 stars upon forty-three plates previously obtained were reduced for the catalogue of the photographic chart.

The great Coudé equatorial has been used whenever possible in lunar photography, in order to complete the series of photographs of the moon required to make a large-scale map of our satellite. The photographs already obtained have been enlarged and reproduced by heliogravure by MM. Fillon and Heuse. The first fasciculus of the photographic chart of the moon, which MM. Lœwy and Puiseux have in hand, containing six sheets, five of which will represent parts of the moon on a scale of 2·60 metres to the lunar diameter, will shortly be issued. The present report contains a heliogravure representing an unenlarged photograph of the moon obtained in February 1894. The picture is a most striking one, reproducing faithfully and beautifully the chief features of the lunar surface.

M. Deslandres has continued his photography of the solar chromosphere. He has also investigated the subject of the displacement in the lines of the spectrum of Jupiter, produced by the planet's rotation. A note upon this subject appeared in NATURE in March 1895 (vol. li. p. 443). In the first measures made by M. Deslandres, the equator of the planet was allowed to lie along the slit of the spectroscope, and the inclination of the lines produced by approach and recession of opposite ends of the equatorial diameter were determined. The method now followed consists in measuring the inclination of the lines in the planet's spectrum with reference to neighbouring lines of terrestrial origin. The mean of the measures thus made gives 48 ± 1 kilometres as the difference of velocity of two opposite points on Jupiter's equator. From the known time of rotation of the planet, and the length of the equatorial diameter, the velocity deduced is 49·6 kilometres. The same method has been applied by M. Deslandres to Saturn's disc and rings.

Reference is made to the spectroscopic photographs of the velocity of Altair in the line of sight. The photographs give evidence of differences in the radial velocity, even when the mean error of observation is considered. These variations have a period of about forty-three days, and a secondary period of about five days. The conclusion arrived at from an examination of the spectra is that Altair is in orbital motion under the influence of one or more unknown bodies. The star β Ursæ Minoris also shows variations of velocity in the line of sight which cannot be accounted for by errors of observation.

In addition to the matters referred to in the foregoing, the usual meridian work, and observations of comets and minor planets, as well as meteorological observations, were carried on during 1895, and the chief results obtained are stated in the report.

CABLE LAYING ON THE AMAZON RIVER.[1]

WHEN it had been decided to connect Belem, the capital of the State of Pará, by means of a subfluvial cable with Manaos, the capital of the State of Amazonas, a preliminary journey became necessary, during which landing-places at the various intermediate stations had to be selected, some reaches of the river explored, as no trustworthy charts exist, and various

[1] Abridged from a discourse delivered at the Royal Institution by Mr. Alexander Siemens.

other details ascertained in order to facilitate the laying of the cable.

This preliminary survey took place in October of last year during the hottest season, when the river was at its lowest; while the cable was laid during January and February of this year, when the rainy season had commenced and the river was rising.

It is extremely difficult to realise the true proportions of this river, but the subjoined comparative table, in which the dimensions of the principal rivers of the various continents are contrasted with those of the Amazon, will help to show the importance of this great system of natural waterways.

With several other large rivers the Amazon shares the fate that its name changes several times during its long course, and that at various times different affluents have been considered to be the true source of the main stream.

Most geographers, however, regard the Marañon as the principal river, a branch of which, called Tunguragua, rises in Lake Lauricocha in Peru in 10° 30′ S. lat., and 76° 10′ W. long.; although the Ucayale, where it unites with the Marañon at Nauta (4° S. lat., 73° W. long), is quite as important as the Marañon.

,, Brazil	3,219,000
,, Europe	3,790,000

If the greatest distance from the mouth is to decide the question, then the source of the Apurimac, an affluent of the Ucayale, can lay claim to being the origin of the Amazon, rising in Peru in 16° S. lat., and 72° W. long.

Along the whole course of the Amazon, commencing at the foot of the Andes, a network of islands and canals is formed on both sides of the river, as the whole country is almost level, and is consequently inundated during the rainy season for hundreds of miles by the rivers flowing through it. The most notable exception to this general state of things occurs at Obidos, where the whole volume of water is compressed into one channel a little over a mile wide, and said to be about forty fathoms in average depth. A sounding taken opposite Obidos, about a third of the distance across the river, showed a depth of fifty-eight fathoms, measured by a steel wire and Lord Kelvin's sounding-machine. As the current of the river averages three knots in the main channel, it is not easy to take soundings by an ordinary lead line; and even with the steel wire an extra heavy weight (33 lb.) has to be employed, or the results are not trustworthy.

Besides the wire sounding-machine a submarine sentinel was used on the preliminary voyage, wherever serious doubts existed about a channel through which the cable was to be laid. This apparatus consists of a small winch from which a wire leads into the water and drags at a short distance behind a piece of wood, shaped like an angle-iron, in a nearly upright position. The wire is not attached directly to the piece of wood, but to a string kite-fashion, and the wood is fitted with an iron foot which, on coming in contact with the bottom of the water, releases one end of the kite-string, so that the wood remains attached to the winch wire with one end only. The consequence is that the strain on the wire is suddenly reduced to a very small amount, and the piece of wood appears on the surface of the river. It depends on the quantity of wire paid out how deep the kite or the sentinel floats, and its action is quite trustworthy, so that it is unnecessary to take soundings by the line or by wire while the sentinel is being dragged by the ship. Usually the sentinel was set at five fathoms, and when it struck a bar the ship was stopped, and a series of soundings taken to ascertain the exact depth of water, and the extent of the shallow place.

A further difficulty in sounding originated from the soft nature of the soil, which for the greater part of the Amazon valley is alluvial clay, and allows the lead to sink into it for several feet. In the narrows there appears, however, a bank of hard clay (called Tabainga) which, unfortunately, blocks nearly all the branches of the narrows, and creates bars all along the course of the Tajipuru, the main westerly waterway connecting to the Gurupá branch of the main river. Occasionally the same hard clay forms shallows in the main river, but as a rule the section of all the channels resembles the capital letter U, *i.e.* the sides are very steep and the bottom flat. In this respect, as in many others, the Amazon differs entirely from the Indian rivers, which build up their beds above the surrounding country, occasionally breaking through their natural banks and seeking a new bed. The Amazon, on the other hand, carries with it only the light clay sediment which forms the soil of the whole valley; and the inducement for the main stream to alter its course is therefore very small, and long straight reaches are the result.

Under these circumstances the largest vessels can ascend the river nearly to the foot of the Andes, but the constantly-changing sandbanks at the mouth of the Amazon proper make this approach of the river dangerous, and the State of Pará is, for obvious reasons, not over-anxious to have the deep channels properly buoyed and surveyed. This forces all the shipping to enter the Pará River, and to pass the narrows if the Amazon is the goal of the journey. In doing the latter, the choice for large ships lies between one of the channels (called Furos) with a bar, where it joins the Tajipuru, and a furo (the Macajubim) which has plenty of water, but which winds about in such a serpentine fashion that only ships with twin screws can pass it unassisted.

These difficulties are, however, much diminished during the rainy season, when the river rises to such an extent as to drive all the inhabitants of its banks into the towns, which have been built wherever a natural eminence secured the inhabitants against the flood. Near the mouth the difference is naturally not so great as higher up, where the influence of the tide is felt less; but at Manaos the difference in level between low river and high river exceeds forty feet.

With all rivers carrying sediment the Amazon shares the peculiarity that its immediate banks are higher than the country lying behind them, and thus we have in the rainy season the spectacle of the main river flowing between two banks covered with dense forest, and immense lakes stretching out on either side of these banks. These do not entirely dry up during the remainder of the year, so that the whole of the Amazon valley really forms a huge swamp covered with a most luxuriant forest, which below Manaos narrows to a broad belt close to the main river with prairies, called Campos, at the back of the forest stretching out to the hills, where the forest recommences. In such a country no land communication of any sort can be attempted, as the tropical vegetation and the annual inundations of the rivers destroy everything that man places in the way of the natural forces. By water, on the other hand, the intercourse between all habitable parts of the country is easy and expeditious since steamers were introduced in the year 1853. Belem, the capital of the State of Pará, lies on a branch of the Pará River, called Guajará, which unfortunately does not share the characteristic shape of the Amazon and the furos, but forms a rather shallow basin in front of the town.

The first station on the main cable is Breves, the centre of the rubber trade of the islands of the lower Amazon, situate in the centre of "the narrows."

In Gurupá, the second station of the main line, the inhabitants expressed their joy at being put in communication with the rest of the world by actively helping in the landing of the first shore end.

During an enforced sojourn near the mouth of the Boinasu, in the midst of the most wonderful combination of islands and rivers, the two naturalists, which the British Museum authorities had kindly sent with the expedition, took full advantage of the opportunity to explore the locality in all directions.

In the rubber-gathering industry, which is at once the wealth and bane of this part of the world, the implements in use are of the most primitive kind, but the average earnings can easily be three pounds per day during the dry season, and the facility of earning so much money with little exertion makes the inhabitants unwilling to engage in more arduous labour.

A narrow path leads from the hut on the water's edge into the forest from one rubber-tree to another, the path eventually returning to the hut. The trees are cut on the morning round, and the rubber is gathered in the afternoon. As soon as it arrives at the hut a fire of oily palm-nuts (*Attalea excelsa*) is lighted, and the thin sap thickened in the smoke For this purpose a paddle is used, on to which the sap is poured with a small earthenware or tin vessel. The smoke soon thickens it, and a new layer is poured on until the well-known flat cakes of india-rubber have been formed.

Owing to the rise of the river during the rainy season most of the huts have to be abandoned, and it can easily be imagined how comfortless they are. Nearly all of them are built on piles, and most of them are thatched with palm-leaves. There is hardly any attempt made to cultivate the soil, such as it is, but everything is imported. The s.s. *Cametense*, in which the surveying party went out, was laden with cabbages, onions, and potatoes, part of which went as far as Iquitos in Peru.

Chiefly owing to this want of provisions, and to the generally careless mode of life, the mortality among india-rubber gatherers is very great.

Everything Bates and Wallace have said of this region remains as true as it was forty years ago, and hardly anything new can be added to their description of the general features of the Amazon valley; but the town of Manaos has completely changed its character since it was made the capital of that region in 1853. A town quite European in its features has arisen in the midst of the forest, and to the benefits of rapid transport, to which it has owed so much, there is now added the characteristic lever of modern progress, the annihilator of space and time—electrical communication.

NOTES ON CLOUDS.[1]

THERE are two points connected with clouds on which I wish to make a few remarks. The first is on the classification of clouds, and the second on the manner in which certain forms of clouds are produced. It may be as well to remark at the outset that the observations are those of an "outsider," being in a department of meteorology to which I have given but little attention, and they have been written with a view of calling the attention of specialists, and getting their opinion on the subject.

It appears to me that in classifying clouds they ought first of all to be divided into two great classes. In the one class should be placed all clouds in the process of *formation*, and in the other those in the process of *decay*. The two classes might be called *Clouds in Formation* and *Clouds in Decay*. We may take Cumulus clouds as an example of the former, and Nimbus of the latter. My observations made on the clouds themselves have shown that there is a difference in the structure of these two classes of clouds. In clouds in formation the water particles are much smaller and far more numerous than in clouds in decay; and while the particles in clouds in decay are large enough to be seen with the unaided eye when they fall on a properly lighted micrometer, they are so small in clouds in formation that, if the condensation is taking place rapidly, the particles cannot be seen without the aid of a lens of considerable magnifying power. In the former case the number of particles falling per square millimetre is small, while in the latter they are so numerous that it is impossible to count them.

It appears that one good end might be served by adopting this classification. It would direct the attention of observers more to looking on the processes going on in *decay* for an explanation of many of the forms observed in clouds. In most books on clouds, when describing the different shapes of clouds, it is almost always assumed that they are in process of *formation*, and the whole explanation of the shapes taken by the clouds is founded on this supposition. Now, it is very evident that very many clouds are in the process of decay, and their forms can only be explained by the processes going on under these conditions.

This brings me to the second point in this communication, namely, the manner in which ripple-marked cirrus clouds are produced. The explanation which has generally been accepted of the formation of this form of cloud is, that the ripple markings are due to the general movements of the air giving rise to a series of eddies, the axes of the eddies being horizontal, and roughly parallel to each other. It is very evident that the air revolving round these horizontal axes, that is, in a vertical plane, will at the lower part of its path be subjected to compression, and at the upper part to expansion. The result of this will evidently be, supposing the air to be nearly saturated with moisture, a tendency for cloudy condensation to take place in the air at the upper part of its path, and it is this cloudy condensation in the upper part of the eddies that is supposed to produce the ripple-like cirrus; each ripple mark indicating the upper part of an eddy. One objection I have always felt to this explanation is, that it is difficult to imagine that the small amount of elevation and consequent expansion and cooling could give rise to so dense an amount of clouding as is generally observed. Any clouding produced in this way one would expect to be extremely thin and filmy. I have for the last few years made frequent observations of these clouds, and I have to admit I have never once seen them in the process of formation, or seen one appear in a clear sky. In all cases that have come under my observation, these ripple clouds have been clouds in decay. They are generally formed out of some strato-cirrus or similar cloud. When we observe these strato-cirrus clouds in fine weather, it will be found that they frequently change to ripple-marked cirrus clouds before vanishing. The process of their formation would seem to be: the strato-cirrus gradually thins away till it attains such a depth, that if there are any eddies at its level, the eddies break the stratus cloud up into parallel or nearly parallel masses, the clear air being drawn in between the eddies. It will be observed that this explanation requires the eddies, but not to produce the clouding, only to explain the breaking up of the uniform cirrus cloud into ripple cirrus.

One thing which supports this explanation is, that lenticular-cirrus clouds are frequently observed with ripple markings on one or more sides of them just where the cloud is thin enough to be broken through by the eddies. If we watch these lenticular-formed clouds under these conditions, we frequently see the ripple markings getting nearer and nearer the centre as the cloud decays; and at last, when nearly dissolved, the ripple markings will be seen extending quite across the cloud. It seems probable that "mackerel" and other cloud forms may be produced in the same way.

The shapes which these ripple cirrus clouds assume are much more varied than is generally supposed. I lately observed a most interesting form in the south of France while the mistral was blowing strongly. There were a few cirrus clouds in the sky at the time, and one of these was rapidly being broken up into irregular ripple forms, but at one point there was formed a most perfectly cylindrical-shaped piece, its length being about twenty times its diameter. The whirling effect of the eddy was very evident by the circular streaking of the clouding. Further, this cloud was evidently hollow, that is, the interior was filled with clear air as the cloud was thinnest along the axis, and it had all the appearance of a revolving tube of cloudy air.

It is not contended here that ripple clouds are never produced in the manner which has generally been accepted, only that so far as my observations go they have never been observed forming in the manner supposed. It is hoped that others will put the explanation here offered to the test of observation, and it is principally with a view of getting others to repeat the observations that this has been written.

[1] Paper read by John Aitken, F.R.S., to the Roy. Soc. of Edin. on May 4.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—In the Mathematical Tripos List published on June 16, Mr. W. G. Fraser, of Queens', is Senior Wrangler, Messrs. Barnes, Carson, and Wilkinson, all of Trinity, are bracketed for the second place, and four members of St. John's, Messrs. Edwardes, Houston, Cook, and Turner, follow in two brackets, fifth and seventh. Miss Longbottom, of Girton, has the twelfth place.

In Part II. seven names appear in the first division of the first class, beginning with Mr. Bromwich, of St. John's, the Senior Wrangler of last year.

Mr. A. C. Dixon, of Trinity College, has been approved for the degree of Doctor of Science, in consideration of his mathe-

matical works. Mr. Dixon was Senior Wrangler in 1886, and is Professor of Mathematics at Galway.

A lectureship in Hausa is about to be founded, in virtue of a benefaction by the Hausa Association. The language ranks with Arabic and Suaheli as one of the most important West African tongues used within the British sphere of influence.

The General Board propose that a Professorship of Mental Philosophy and Logic, with a stipend of £700 a year, should be forthwith established. Prof. Sidgwick has generously offered to accept a diminished stipend of £500 a year for the next six years in order that funds may be available for this purpose.

The Tyson Medal for Astronomy has been awarded to Mr. E. T. Whitaker, of Trinity.

Mr. W. Mather has received the thanks of the University for a valuable gift to the Engineering Laboratory of an experimental steam-engine and dynamo.

A Latin letter of congratulation to Lord Kelvin on the jubilee of his Professorship at Glasgow was approved at the Congregation on June 11, and was ordered to be sealed with the Common Seal of the University and presented to him by the University delegates to Glasgow.

The Syndicate on Women's degrees was appointed without opposition, and have already held their first meeting. Their report will not be issued until next Term.

The following appointments have been made in the Northern Polytechnic Institute, Holloway:—Mr. Hubert A. Garratt, Senior Lecturer in Engineering, University College, Bristol, to be Head of the Engineering Department; Mr. V. A. Mundella, Assistant Lecturer in Physics and Electrical Engineering, Durham College of Science, Newcastle, to be Head of the Physics and Electrical Engineering Department; Dr. Thomas Ewan, Assistant Lecturer in Chemistry, the Yorkshire College, Leeds, to be Chief Assistant in the Chemical Department. Other recent appointments are:—Dr. G. Frege to be Professor of Mathematics at Jena; Dr. Lickfett to be Director of the Hygienic-bacteriological Institute at Danzig; Dr. Scholl to be Extraordinary Professor of Chemistry in the Technical High School at Karlsruhe. Mr. E. A. Gardner, formerly Director of the British School at Athens, to be Yates Professor of Archæology in University College, London; Dr. Paul Eisler to be Extraordinary Professor of Anatomy at Halle; Dr. L. Joubin to be Professor of Zoology, and Dr. H. Prous to be Extraordinary Professor in Lille University; Dr. Theobald Smith to be Professor of Comparative Pathology in Harvard University.

The Technical Instruction Committee of the North Riding County Council some time ago substituted a system of individual instruction in cheese and butter making at the farm-house of any farmer who desired it, for the more commonly adopted travelling dairy school. In addition to this method of instruction they have agreed to a scheme whereby a permanent dairy school will be opened at Helmsley in the course of the present month. The school is being built by the Earl of Feversham, and is to be placed at the Committee's disposal, who are making themselves responsible for the proper fittings and apparatus. It is confidently anticipated that the school, which will be styled the "Ryedale Dairy School," will be much used and greatly appreciated.

On Thursday evening last it was resolved by 332 votes to 83, that boroughs of not less than 20,000 population should form separate educational authorities. This will mean, as the Vice-President of the Council pointed out in his speech on this amendment, that in addition to the 128 authorities which there would have been as the Bill originally stood, we are to have 241 more authorities added, that is, provided the amendment passes the House of Lords. Further, since there is no doubt populous urban districts will claim to be treated like municipal boroughs, and it seems only reasonable to suppose that such will be granted similar powers, forty-nine more authorities will be brought in, making a total of 418 separate centres for the Education Department to deal with. In some cases the result will be extraordinary; for example, in Lancashire there will be some forty-two different educational authorities. The extent to which the work of the County Councils would suffer should this concession of the Government become law, can only be appreciated by those who know the spirit in which small local authorities approach any matters pertaining to secondary education.

SOCIETIES AND ACADEMIES.

London.

Physical Society, June 12.—Captain Abney, F.R.S., President, in the chair.—Mr. Campbell read a paper on the measurement of very large and of very small alternating currents. The author advocates the use of air-coil transformers for measuring voltages and currents which are either above or below the range of the instruments available. If an attempt is made to measure the current in the primary of an air-coil transformer by observing the voltage on an open circuit secondary, it is found that the readings depend on the frequency. In order to overcome this difficulty the author uses a closed secondary with a very high inductance. In this case the primary current is proportional to the secondary current, which latter may be measured by an ammeter. The author has also investigated the case of transformers with iron cores, and of which the inductance of the secondary is large. In the case of a ring transformer with a closed magnetic circuit, if the load on the secondary consisted solely of a Kelvin 100-ampere balance of very low resistance, the ratio between the primary and secondary currents is practically constant. With an open magnetic circuit transformer, however, this is not found to be so, as the ratio between the primary and secondary current varies considerably with the frequency. Mr. Blakesley said that the author's arrangement could only be used for measuring the *current* in the primary. He (Mr. Blakesley) had shown how to measure alternating currents by means of dynamometers, and without the necessity for any special apparatus. Mr. Griffiths exhibited and described his improved form of resistance box. This resistance box has many novel features: (1) It permits of all the coils being compared with one another, without the use of standard coils, and with great ease and rapidity. Hence it is sufficient at any time to compare any one of the coils with a standard to obtain the correction to be applied to all the coils. (2) The bridge wire can be calibrated by means of the box itself. (3) The temperature of the coils can be accurately determined, since they consist of bare platinum-silver wire wound on mica and immersed in an oil bath, which bath is kept stirred. (4) The resistance of the leads from the box to the object being tested is eliminated, as well as any error due to a change in this resistance with temperature. (5) The coils are arranged according to a binary scale, and the author claims that it is possible to measure resistances up to 105 ohms, to within 0·000001 ohm. (6) All the coils, after being adjusted, have been heated to redness and allowed to cool slowly, so that all strain has been removed from the wire. (7) By having a separate pair of blocks for each plug, it is impossible for the insertion of one plug to affect the fit of a neighbouring plug. The plugs themselves are so made that no part of the plug is wider than the top of the hole, and so it is impossible to wear a "shoulder" on the plug. Prof. A Gray said that Mr. Griffiths had discovered and remedied all the weak points of the ordinary form of bridge. Lord Kelvin had ordered the paraffin to be melted off the coils of one of his resistance boxes, and it was found that the resistance of the coils altered considerably, owing, no doubt, to the strain to which the wire had been subjected, when imbedded in the solid paraffin. Lord Kelvin had made coils without paraffin, and was specially in favour of the use of the binary scale. Prof. S. P. Thompson said he considered the binary scale the weak point of the author's arrangement, since it did not permit of ratios other than 1 to 1 being employed. Mr. Campbell asked what current could safely be passed through the coils. The author in his reply said that he believed it to be a great mistake to employ any ratio for the arms other than 1 to 1.—Prof. S. P. Thompson read a communication on Röntgen rays. The author, after describing the various forms of tubes he had made with a view of discovering the best form for the production of Röntgen rays, gave an account of the experiments he had made to try and obtain some indication of polarisation. In this connection a large number of crystals have been tested, but the experiments have all given negative results. The author exhibited an electroscope with aluminium leaves and enclosed in a wire-gauze screen, to protect it from the influence of outside electric changes, by means of which he was able to show the discharge of a positively or negatively electrified body by means of the X-rays. A method of obtaining dust figures by the discharge of an electrified body by the X-rays

was shown, and some of the results which have been obtained were exhibited. All attempts to obtain true reflection have failed, although it appears as if most bodies, including air, are capable of giving diffuse reflection.—Dr. Shettle, who was announced to give a paper on Röntgen rays, explained that he had just discovered that the effects he had intended to describe were due to red light which had penetrated his dark room.—Prof. du Bois said that Galitzine had found that Röntgen rays were polarised by tourmaline, a special form of developer being employed. The behaviour of tourmaline to light waves presents some curious features, for if the wave-length is increased a point is at length reached where the ordinary and extraordinary rays are equally absorbed. For greater wave-lengths the ordinary conditions are reversed. If the Röntgen rays are not homogeneous, the contradictory results obtained by different observers might be due to the fact that they were working with rays which were differently absorbed by tourmaline.—Mr. Swinton said he had tried the effect of heating the kathode, and had obtained results which were similar to those obtained by the author. Mr. Swinton further said that he had found that the blue luminescence sometimes observed depended on the size of the kathode. With tubes in which the kathode was almost a complete hemisphere it was impossible to eliminate this blue luminescence.—Mr. Appleyard suggested the performance of the experiments under the surface of a dielectric.—Prof. Gray said he had obtained some indication of regular reflection, but nothing definite. The author in his reply said that it had been found that if the Röntgen rays are reflected from a surface of sodium in vacuo the amount reflected is a minimum for normal incidence, and increases at oblique incidence. Comparing this behaviour with that of ultra-violet light, it supports the idea that the Röntgen rays consist of transverse vibrations. The Society then adjourned till June 26.

Geological Society, May 27.—Dr. Henry Hicks, F.R.S., President, in the chair.—The President announced that a portrait in oils of the late Prof. Huxley had been presented to the Society by Sir John Evans, K.C.B., F.R.S.—On the Pliocene deposits of Holland, and their relation to the English and Belgian crags, with a suggestion for the establishment of a new zone "Amstelien," and some remarks on the geographical conditions of the Pliocene epoch in Northern Europe, by F. W. Harmer. The author drew attention to some papers by Dr. J. Lorié, of Utrecht, describing the strata met with in some deep borings in Holland, which showed that the Newer Pliocene is in that country nearly 500 feet thick, and that it had been depressed more than 1000 feet below its original position. He inquired whether this subsidence could be connected with the elevation of the Older Pliocene in Belgium and Kent, and how far these earth-movements could be traced in East Anglia and influenced the deposition of the English crag. He gave particulars of the alterations in level which have taken place during and since the Crag period in England and on the continent, showing that the two movements of upheaval and subsidence have much in common, and especially that they regularly increase in degree to the north and south respectively.—The *Lingula*-flags and igneous rocks of the neighbourhood of Dolgelly, by Philip Lake and S. H. Reynolds.—The Kildare inlier, by S. H. Reynolds and C. I. Gardiner. The area described in this paper is occupied by four prominent hills composed of lower palæozoic rocks rising as an inlier from beneath carboniferous beds. The authors gave the following succession of rocks in descending order. (6) Green and grey micaceous grits and shales of Dunmurry. (5) Red and black shales. Gap: no exposure seen. (4) Limestones of the chair of Kildare. (3) Contemporaneous igneous rocks. (2) Fossiliferous ash of Grange Hill House. (1) Green gritty shales (unfossiliferous).

CAMBRIDGE.

Philosophical Society, May 25.—(*a*) On the spectroscope used in connection with the 25-inch refractor; (*b*) on a suggestion for a form of spectroheliograph, by Mr. H. F. Newall. On the period of the earth's free Eulerian precession, by Mr. J. Larmor. The following general proposition is easily established; it has been suggested by the recent memoirs of Prof. Newcomb and Mr. Hough. Consider any solid body, for example the earth, in rotation about its axis of greatest moment of inertia: when the body is not absolutely rigid, the period of the small free precessional motions of the axis of rotation will depend in part on its elastic yielding to the centrifugal force; but in all such cases, whether the body is homogeneous or not, whether the elasticity is perfect or imperfect, this precessional motion will be the same as that of a body absolutely rigid, with its materials distributed in the configuration which the actual body would assume, on the supposition that it remains perfectly elastic, were it relieved of the centrifugal force of rotation. Taking the case of the earth, in which the equatorial moments of inertia are all equal to A, while the axial one is C, the ordinary forced astronomical precessions give the value of $(C-A)/C$; while knowledge of the variation of terrestrial gravity gives $C-A$; so that C and A are separately known. The period of the free Eulerian precession gives $(C'-A')/A'$, where C' and A' are the moments of inertia which the earth would have were the strain corresponding to centrifugal force removed. In so far then as this free period can be reliably disentangled from the actual observations of changes of latitude, which are also affected by unknown irregular variations due to meteorological causes, and so more or less of an annual character, we derive from it a knowledge of $C'-A'$; thereby obtaining an additional *datum* for discussions relating to the constitution of the earth's interior. This is on the supposition that the earth is wholly solid. The influence of the surface waters can, however, be estimated by the same principle, as they are in the main deep enough to make an equilibrium theory applicable. It appears that, if the actual earth were absolutely rigid, and wholly covered by an ocean, the mobility of this ocean would lengthen the period of free precession by about 14 per cent. But this superior limit is reduced both by the limited extent of the ocean and by the yielding of the solid earth; so that, on an outside estimate, not more than 6 or 8 of the actual 40 per cent. of lengthening of the period can be due to mobility of the surface waters. On this equilibrium theory, an amplitude of a third of a second of arc in the Eulerian precession would produce a tidal component, of the same period, whose amplitude would in middle latitudes be about half an inch; which is just the kind of result that has been derived from examination of the tidal observations in Holland and on the east and west coasts of North America. The influence of possible fluidity of a portion of the interior has been fully developed by Mr. Hough, the results agreeing with indications virtually given by Lord Kelvin so long ago as 1876, and published in the British Association Report for that year. The conclusion drawn by Mr. Hough from the Chandler period, that, for the small stresses involved, the interior of the earth is in the main perfectly elastic and about as rigid as steel, is in accord with the recent observations by seismologists of what is probably the time of propagation of earthquake disturbances from Japan to Europe in a direct line across the earth's interior.—Note on a point in theoretical dynamics, by Sir Robert Ball. Let α be a screw about which a free rigid body is made to twist in consequence of an impulsive wrench administered on some other screw η. Except in the case where α and η are reciprocal it will always be possible (in many different ways) to design and place a rigid body so that two arbitrarily chosen screws α and η will possess the required relation. Let now β and ζ be two other screws (not reciprocal); we may consider the question as to whether a rigid body can be designed and placed so that α shall be the instantaneous screw corresponding to η as an impulsive screw, while β bears the same relation to ζ. It is easy to see that it will not generally be possible for α, β, η, ζ to stand in the required relations; they must in some way be restricted. It is the object of the author's note to show that the restrictions are two in number, and to set down what they are.

EDINBURGH.

Royal Society, June 1.—Prof. Copeland in the chair.—Prof. Tait read a paper on the linear and vector function. We speak of fluid motion as being "differentially irrotational" when there is a velocity potential, and as "rotational" when there is a vortex. In the first case, the strain involved is pure, *i.e.* there are three rows of particles, at right angles to one another, whose directions are momentarily unchanged. In the second case, one such row of particles alone exists. But there is, when we look at the matter from the point of view of the roots of the strain-cubic, a third case—where there are three rows of particles, *not* generally at right angles to one another. Prof. Tait showed that such a strain is, in general, the result of the superposition of two successively applied, but different, pure strains. Thus, comparing the non-vortex states of a small element of a fluid at three successive instants, a portion, cubical at the instant A, may be found, such as to be brick-shaped, without change of direction of its edges, at B. Similarly from B to C. But to

compare A with C, we have a definite parallelepiped whose edges remain unchanged in direction.—Mr. R. C. Mossman gave the first part of a communication on the meteorology of Edinburgh, in which he dealt with the mean values of the climatic elements for each day of the year, basing his inquiry on over a million observations. The non-instrumental records extended over 125 years, and the daily sunshine means over 30, the average of the nineteen classes of observation being about 80 years. As regards pressure, the maximum was from April 7 to July 3, and the minimum on November 26. For temperature the maximum was an average of 59°·3 on August 8, while January 8 was the coldest, the mean temperature being 36·0. The curve of rainfall showed that the seven days ending April 18 were the wettest days in the year, thus confirming the popular belief in the Lammas floods. Mr. Mossman described in detail the climatic features of each month, and showed how these reacted on each other. An interesting result was the recurrence of similar types of weather at the same time each year.—Mr. Malcolm Laurie read a paper on the nutrition of the embryo in scorpions. The variation in the modes of development in different genera of scorpions is very large. The primitive form seems to be a large egg with much food yolk, and is found in *Euscorpius* and the *Buthidæ*. This egg develops in the ovarian tube. In other *Juridæ* the egg is yolkless, though appearing to be a considerable size owing to the surrounding embryonic membranes. In the *Scorpionidæ* the egg is entirely without yolk, and develops in a diverticulum of the ovarian tube. Various contrivances exist for the better nourishment of the embryo during the later stages of development. Nourishment, secreted by the cells of the diverticulum and by a solid cord of cells (appendix) in which it terminates, is always taken in through the mouth, which is early developed. In addition to this, in *Ischnurus*, the cheliceræ grow into long root-like processes which lie among the cells of the appendix, and seem to absorb nourishment from them. In *Hormurus* a similar function is performed by the chelæ, while in the *Scorpionini* the cheliceræ grasp a cord of cells coming from the centre of the appendix, and masticate it. In these last forms there are also present dorso-lateral out-growths of the segments of the body, which appear to act as surfaces for absorbing nourishment directly from the surrounding maternal tissues. This arrangement is carried still further in *Opisthophthalmus*, where there are two long processes, one from the prostomium, and the other from the back of the carapace, which run out among the maternal tissues.

DUBLIN.

Royal Irish Academy, June 8.—Dr. J. Kells Ingram, Vice-President, in the chair.—Mr. Charles J. Joly read a paper on quaternion invariants of linear vector functions and quaternion determinants. This was a supplement to a paper read before the Academy in December 1895, and published in their *Transactions* (vol. xxx. part 18). From given linear vector functions others are derived by repeated multiplication in any order. The Hamiltonian and other quaternion invariants of these new functions are expressed as the quotients of two determinants with vector constituents. Their scalar parts having been considered in the previous paper, their vector parts are now reduced to the results of operation on the spin-vectors of the given functions, and of one function of each of certain cyclical groups of the derived functions. Examples and interpretations are also given of determinants with quaternion constituents in the expansion of which the order of the rows is preserved.—Mr. Henry Dixon read a paper on the osmotic pressures in the cells of leaves. The method adopted for estimating the osmotic pressures existing in the cells of leaves, consisted in enclosing a branch bearing a number of leaves in a strong glass cylinder, capable of resisting high gas pressures (*e.g.* 50–100 atmospheres). The ends of this cylinder consist of stout brass castings, drawn together on the cylinder by means of bolts and nuts. The upper end is furnished with suitable couplings for connection with an air compression pump or an iron bottle containing liquid CO_2. The lower end is perforated and admits of the branch, to be experimented with, being sealed into it. The cut end of the branch dips into a vessel containing a weighed amount of water, which is placed below the glass cylinder. When the pressure in the cylinder is raised, it is found, that at a certain pressure, the leaves begin to collapse and lose their turgescence, and that water is forced down from them into the vessel beneath. By a series of experiments on each branch, a certain critical pressure is found which just balances the osmotic pressure of the cells, but which neither causes their collapse nor permits of their drawing up water from below.

PARIS.

Academy of Sciences, June 8.—M. A. Cornu in the chair.—Theory of the flow of water in conduits, by M. J. Boussinesq.—On the effect produced by the ring in iron in dynamo-electric machines. Reply to the note of M. Potier, by M. Marcel-Deprez.—Study of melted vanadium and its carbide. by M. H. Moissan. Vanadium pentoxide, reduced by carbon in the electric furnace, yields an ingot of metal which always contains an appreciable amount of carbon. If the time of heating is as short as possible, a metal containing only 5 per cent. of carbon can be obtained; by prolonging the time of heating the percentage of carbon increased to 18·5 per cent., indicating the formation of the carbide VC. The carbide is not attacked by water at the ordinary temperature. Vanadium forms alloys with iron, copper, and aluminium, but not with silver.—On a new method of preparing alloys, by M. H. Moissan. Alloys of refractory metals can be prepared by projecting a mixture of the oxide with powdered aluminium into a bath of liquid aluminium. The heat set free by the oxidation of the aluminium is sufficient to carry on the reaction. Alloys of aluminium with nickel, molybdenum, tungsten, uranium and titanium have been obtained in this way.—On the nature of the chemical processes involved in muscular action, by M. A. Chauveau. Summing up the results of a series of experimental researches on the relation between the energy given out as muscular work and the energy absorbed as food.—On the value as food of bread made from screened flours, by M. A. Girard. Analyses of flours of various qualities, from which the conclusion is drawn that the ideas generally held concerning the inferior nutritive power of fine white bread as compared with brown bread, are fallacious; both kinds of bread containing practically identical amounts of gluten and of phosphates.—On the theory of gases, a letter from M. Boltzmann to M. Bertrand, continuing the discussion concerning the validity of Maxwell's formula for the distribution of the velocities of the molecules at a given instant.—Reply to the preceding by M. Bertrand, by whom Maxwell's theorem is held to be obviously inaccurate.—The influence of the temperature of the freezing mixture upon cryoscopic measurements, by M. F. M. Raoult. Starting from simple considerations an expression is obtained giving a correction for super-cooling in cryoscopic measurements. This formula is identical with that given by MM. Nernst and Abegg, but the practical application of it given by the latter, is open to criticism. A very simple and accurate method is given by M. Raoult, who shows that the temperature of the bath is without practical effect upon the laws previously published. In the few cases where the correction is necessary, it is easily measured and applied.—On differential equations of the first order, by M. P. Painlevé.—On the regulation of motors, by M. L. Lecornu.—Observations on the errors due to variations of temperature in geodesic instruments, by H. F. A. Aimo. A discussion of the effect of temperature upon the size and shape of the air-bubble in levelling instruments.—On the spectra of metalloids in fused salts, by M. A. de Gramont. Measurements of the lines due to sulphur in metallic sulphides.—Contributions to the study of absorption by porous bodies, by M. Lachaud. An experimental study of the amounts of quinine, methyl-violet, salicylic acid, tannin, dextrine, and gelatine remaining in solution after treatment with animal black.—On the estimation of potassium, by M. Charles Fabre. The platinochloride is reduced in warm aqueous solution by magnesium powder, and the resulting chloride titrated with standard silver solution.—On the heat of vaporisation of formic acid, by Miss D. Marshall. By comparison with benzene as a standard substance, the value for the latent heat of vaporisation of formic acid was found to be 120·4, a number practically identical with that (120·9) calculated from M. Raoult's formula containing the rate of variation of vapour pressure with temperature, the absolute boiling point, and the molecular lowering of the vapour pressure as the experimental data.—Combinations of antipyrin with oxybenzoic acids and their derivatives, by MM. G. Patein and E. Dufau.—On lighting by acetylene, by M. G. Trouvé. A description of the methods used for the practical preparation of acetylene for lighting purposes from calcium carbide.—On the composition of the red pigment of *Amanita muscaria*, by M. A. B. Griffiths.—On the larval metamorphoses of the *Phoronis sabatieri*, by M. Louis Roule.—Description of a new genus of simple Ascidia, Gamaster Dakarenis, by M. A.

Pizon. This genus resembles generally the *Eugyra*, from which however it is clearly differentiated by the structure and position of the genital organs.—On the existence and development of the eggs of the sardine in the waters of Concarneau, by MM. Fabre-Domergue and Biétrix.—The latent life of grain, by M. V. Jodin.—Remarks on the preceding communication, by M. Armand Gautier.—Analysis of one of the meteoric stones that fell at Madrid, February 10, 1896, by M. S. B. Mirat. The meteorite consisted practically of the silicate of magnesium and iron, containing also estimable quantities of aluminium, nickel, and calcium.—Artificial reproduction of malachite by a new method, by M. A. de Schulten.—On the liassic domes of the Zaghouan and of Bou-Kournin, by MM. E. Ficheur and E. Haug.—The part played by the hind limbs in the motion of the horse, by M. Le Hello.—On a relation between muscular energy and sensibility, and on the laws of variation of this energy with respect to time, by M. C. Henry.—Photographs by the X-rays of a bullet in the brain, by MM. E. Brissaud and Londe.

NEW SOUTH WALES.

Linnean Society, April 29.—Mr. Henry Deane, President, in the chair.—Theoretical explanations of the distribution of southern faunas, by Captain F. W. Hutton, F.R.S. After reviewing the various theories which have been offered to explain the difficult and intricate problem of the distribution of southern faunas, the author pointed out that the supposition that the ancestors of certain groups migrated from the northern into the southern hemisphere by the present continents, and have since then become extinct in the north, explained a good deal, but failed to give a full and satisfactory explanation of the whole of the facts. Moreover the members of the fauna unaccounted for are old forms, and consequently the means of communication which served them must long ago have been destroyed. To the author a fatal objection to the theory of migration by way of an Antarctic continent is offered by the following consideration. Aplacental mammals—both Multituberculata and Polyprotodontia—existed in Europe and North America in the Triassic and Jurassic periods, and these Polyprotodontia were, no doubt, the ancestors of the living Polyprotodontia of Australia. In the Eocene strata of Patagonia remains of a large number of Polyprotodontia have been found which are far more closely related to the Polyprotodontia of Australia than to the Mesozoic forms of Europe and North America; consequently a direct land communication must have existed between these two southern countries. Now there is strong geological and palæontological evidence that no land ridge existed between North and South America during the Mesozoic and early Cainozoic eras; consequently it must be assumed that the southern forms migrated through the Malay Archipelago; and, if they went to Patagonia by means of an Antarctic continent, they must have passed through Australia. But mingled with the Eocene marsupials of Patagonia there are a number of Eutheria of typically South American character without any northern forms of *Artiodactyla*, *Carnivora*, or *Insectivora*; and it is hardly possible that these should have passed through Australia without leaving any record behind. The theory of the former existence of a South Pacific Mesozoic continent, first suggested by Huxley, seemed to be the only theory left. It not only explains the origin of the Australian and South American marsupials, but also the almost simultaneous appearance of different Eutherian mammals in North and South America. It must be supposed that this continent threw off first New Zealand, then Australia, then Chili, and finally disappeared under the waves. At a later date, New Zealand must have formed part of a large island joined to New Caledonia, but not to Australia. The objections to this theory are geological rather than biological, involving the doctrine of the persistence of continental and oceanic areas upon which geologists are not agreed; and such objections are equally applicable to the theory of an Antarctic continent.—Report on a Bone Breccia deposit near the Wombeyan Caves, New South Wales: with descriptions of some new species of marsupials, by Dr. R. Broom. A detailed examination of this deposit from which *Burramys parvus* and *Palæopetaurus elegans* have already been described by the writer, adds considerably to our knowledge of the smaller marsupial fauna of the later Tertiary period. Of existing forms there have been found *Petaurus breviceps*, *Dromicia nana*, *Phascologale flavipes*, *P. penicillata*, and some detached teeth referred to *Thylacinus cynocephalus*. Besides these are found a presumably new species of *Macropus* for which the name of *M. wombeyensis* is proposed, a new species of *Pseudochirus* (*P. antiquus*), a new species of *Perameles* (*P. wombeyensis*), and an extinct variety of the existing *Potorous tridactylus*. A few bones of a large *Echidna* are referred to *E. oweni*. There are also innumerable remains of bush rats (*Mus* sp.), together with a few bones of small birds and lizards.—The entomology of Australian grass trees (*Xanthorrhœa*), by W. W. Froggatt. The life-histories or habits of a number of insects which either breed in the stems of the grass tree or feed upon its foliage were described.—On the *Galaxias* from Mount Kosciusko, by J. D. Ogilby. After reviewing its history and describing the species (*G. findlayi*, Mcl.) from a fine series, obtained from streams on both watersheds of the Australian Alps, the author gave an account of the curious distribution of this fresh-water family of fishes, with special reference to its Antarctic origin, and concluded with a list of the known forms, holding that far too many species had been made by naturalists who relied too much on contour and coloration, both of which characters are most inconstant.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—An Elementary Treatise on the Integral Calculus: Dr. B. Williamson, 7th edition (Longmans).—Im Australischen Busch und an den Küsten des Korallenmeeres: Prof. R. Semon (Leipzig, Engelmann).—A Manual of Mending and Repairing: C. G. Leland (Chatto).—Macmillan's Geography Readers, Book VI. (Macmillan).—Arithmetic for Promotion, Scheme B.: Lock and Macdonald, 4 Parts (Macmillan).

CLOSELY ALLIED "SPECIES."

Monographie der Gattung Euphrasia. Von Dr. R. von Wettstein. 4to. Pp. 316. With 14 plates and 4 maps. (Leipzig: Wilhelm Engelmann, 1896.)

EUPHRASIA is one of those genera exhibiting a very limited range of variation, as compared with *Ranunculus*, *Senecio*, *Solanum* or *Euphorbia*; yet abounding in closely allied forms, concerning the rank of which there is great diversity of opinion amongst botanists. Bentham and Hooker in their various works, including a monograph of the genus by the former, estimate the number of species at about a score, whilst the author of the monograph under consideration defines nearly a hundred. Whatever our opinion may be respecting the utility of this extreme subdivision, most of us will agree that a profound study of the manner and extent of this limited kind of variation should furnish some interesting results. Moreover the genus *Euphrasia* is admirably suited for this purpose, because it is possible to have the entire plant in all cases.

First, with regard to the utility or convenience of naming such closely allied forms, whether they be ranked as species or varieties. Names are given, of course, as a means to an end. The botanist names his species and the florist his varieties, and there seems no reason why a specialist should not carry his naming as far as his studies lead him. Few may care to attempt to follow him, and he may be impossible to follow, as some of the hieraciologists of the present day are; but no harm is done, no confusion arises. The generally-accepted application of the name *Euphrasia officinalis* is not destroyed by giving names to the various forms it presents. But when the author claims for them that they are "good species," because they are constant under cultivation, or because they have a wide range, or for some other reason we reach a debatable point.

Euphrasia is a genus of small, slender annual and perennial herbs, parasitic on the roots of other plants, chiefly on grasses and sedges, according to Wettstein and other investigators. Bentham divided the species into three sections, which are practically adopted by Wettstein; and these sections inhabit as many widely separated geographical areas. First there is the *officinalis* group, which is confined to the northern hemisphere. Then there is a group restricted to Australia and New Zealand, with the exception of a single species inhabiting Mount Kinabalu, in North Borneo. The third group inhabits western South America, from about 15° S. lat. to Cape Horn. The Bornean species, and another in the Andes of Peru, are the only ones found within the tropics. The total absence of the genus in Africa, the African islands, the mountains of South India and Malaya, with the one exception noted, is a remarkable fact, especially as the genus reaches the north shores of the Mediterranean from end to end, and the Azores, where there is a very distinct endemic species. In eastern North America the genus extends as far south as the north shores of the lakes; it is absent from the centre, and its southern limit in the west is the northern part of the Rocky Mountains. But by some mischance Dr. Wettstein has located the White Mountains of New Hampshire somewhere in Utah! At least he gives the White Mountains as the locality of the species in the text, whilst on his map it occupies the isolated position indicated.

The geography is weak in other places, more especially in the arrangement of the localities in Central Asia. Indeed the author has by no means made the most of the geographical aspects of the question. He has one map showing the general distribution of the genus, and three others showing the areas of the principal northern species; but the explanatory text is altogether insufficient, considering the small scale of the maps. It is interesting to note that many of these critical species have a wide area, and few are really very local. *E. stricta* has two pages of synonyms and seven pages of localities, from which it would appear that the author has examined some thousands of specimens. *E. rostkoviana*, a very common and widely-spread species in Europe, has also been found in Canada, whither it may possibly have been taken with grass-seed.

Without sharing the author's views on species, concerning which he is very confident, I would strongly recommend his monograph for study. It has been considered worthy of a De Candollean prize.

W. BOTTING HEMSLEY.

THE AUTOBIOGRAPHY OF PROFESSOR W. C. WILLIAMSON.

The Reminiscences of a Yorkshire Naturalist. By the late William Crawford Williamson, LL.D., F.R.S. Edited by his Wife. Pp. xii + 228. (London: George Redway, 1896.)

IN the "Reminiscences of a Yorkshire Naturalist," Prof. Williamson has left an autobiographical sketch, containing much that is of general scientific interest, and many delightful records of his own personal history. This simple story of a student's life, which Mrs. Williamson has done wisely to publish in its original form, takes us back to a period which, to the present generation of students, suggests the dawn of modern science.

These reminiscences link, in a picturesque and striking manner, the past with the present. In speaking of his boyhood spent by the Scarborough cliffs, Williamson describes how he examined, with a pocket-lens, the little cups at the tips of *Polytrichum* stems, and wondered whether the reproductive organs, which so many botanists were in search of, were enclosed within these cups. His graphic description of the Father of English geology, recalls the infancy of geological science. As a boy he remembered William Smith, with "the drab knee-breeches and grey worsted stockings, the deep waistcoat with its pockets well furnished with snuff, . . . and the dark coat with its rounded outline and somewhat quakerish cut." It was during his apprenticeship to Mr. Weddell, a Scarborough medical practitioner, that he first contributed to palæo-botanical literature; many of the plates in Lindley and Hutton's "Fossil Flora" were drawn by the young

naturalist at one end of his master's kitchen table, "whilst the housekeeper was occupied at the other end with the several processes of providing the day's dinner." At the age of seventeen, Williamson wrote an important memoir on a tumulus near Gristhorpe Bay, which called forth a letter from Prof. Buckland praising the article, and prophesying that the author's name would "figure in the annals of British science." Passing from these early days of youthful enthusiasm and the pursuit of natural history in all its branches, and over many years of activity in zoological and medical work, we come to the latter part of Williamson's career. The memoirs on the Coal-measure plants, published in the *Philosophical Transactions*, between the years 1870 and 1893, furnish a splendid record of original work, which will always rank among the most important additions to botanical knowledge during the later decades of the present century. It would be difficult to find a more striking illustration of the continuance of vigorous industry, and the power of adaptability to modern methods, than is afforded by the palæobotanical writings of a man whose early days were spent before modern science began.

Did space permit, one might quote numerous passages in which recollections are given of the "sober-minded quaker John Dalton," and of the first meeting with Joule, "a young and extremely unassuming man." The autobiography gives us an epitome of the advance of scientific thought during the present century, with the added charm and freshness of a personal history of the almost ideal scientific career of a genuine naturalist. "Writing these reminiscences of his life's work, was one of the pleasures of Dr. Williamson's later years"; and we are grateful to Mrs. Williamson for giving us the opportunity of sharing the enjoyment of so fascinating a retrospect.

It is a matter of regret that Dr. Williamson's name does not appear in the title of the book; it would have afforded a better index to the interesting contents.

A. C. S.

OUR BOOK SHELF.

Die Protrophie, eine neue lebensgemeinschaft in ihren auffälligsten erscheinungen. Von Arthur Minks. (Berlin: Friedländer and Sohn, 1896.)

DR. MINKS is already well known as the author of several treatises on the biology and morphology of Lichens, in each of which the ideas set forth are quite original, and at the same time directly opposed to modern views regarding the structure presented by this group of plants. The present contribution must be considered as part iii. of "Contributions to a knowledge of the structure and life of Lichens," of which the previous parts appeared in an Austrian scientific publication (*K. K. zool.-bot. Gesell. zu Wien*). The present, preceded by a digest of the leading ideas embodied (*Oester. Bot. Zeitschr.*, 1896, p. 50) appears as an independent publication. The previo'us parts contain, amongst other new views, the ptatement that many species considered as valid by slichenologists, are the outcome of parasitism between two or more originally distinct species, the product being a pseudo-species, differing in structure and general appearance from the species concerned in its production. In the book under consideration, the contents of which could not be understood without a knowledge of the author's previous views and theories, we are introduced to a second method which, as before, results in the wholesale production of what may be termed pseudo-species, due to the intermingling and gradual changing of the layers of the thallus. This change is said to be due to "Protrophie"; a statement which must be accepted in good faith. The definition given would be next to meaningless in English, hence it is offered in the original language.

"Ich erachte es für statthaft, die Unselbstständigkeit, die nur den Anfang des Lebens betrifft, daher auch nur für diese Zeit der schützenden und unterstützenden Flechte zur Einleitung und Sicherung von dessen hauptsächlicher Dauer in aller Selbstständigkeit bedarf, unter Protrophie zu begreifen und die dazu bestimmten Flechten als Lichenes protrophici zu bezeichnen."

The most remarkable circumstance in connection with these supposed discoveries is the fact that the author was enabled to utilise herbarium specimens for his researches, and had not to resort to the more laborious and exact method of pure cultures. G. MASSEE.

Mathematical Papers read at the International Mathematical Congress held in connection with the World's Columbian Exposition, Chicago, 1893. (New York: Macmillan and Co.)

THIS book, which is an excellent specimen of mathematical printing, constitutes vol. i. of "Papers published by the American Mathematical Society." The 400 pages contain thirty-nine papers. German and American mathematicians are the largest contributors; there are a few pages from France, Italy, Austria and Russia also, but the mathematicians of England are not represented. Papers of great interest are given by Dr. Schönflies, "Gruppentheorie und Krystallographie"; by Dr. Heinrich Burkhardt, "Ueber einige mathematische Resultate neuerer astronomischer Unsuchungen, insbesondere über irreguläre Integrale linearer Differentialgleichungen"; by M. Maurice d'Ocagne, "Nomographie: sur les équations représentables par trois systèmes rectilignes de points isoplèthes"; by E. H. Moore, "A doubly infinite system of simple groups." Prof. Felix Klein, of Göttingen, whose work at the Congress has been already published in a separate volume, is only represented here by two short communications, one on "The Present State of Mathematics," the other on "The Development of the Theory of Groups during the last Twenty Years." They are of the nature of lightning sketches by a master hand.

The book is an evidence of the formation, gradual but sure, of an American school of mathematicians which, at first mainly inspired by Cayley and Sylvester, appears now to be coming under the influence, principally, of modern German methods.

Modern Optical Instruments and their Construction. By Henry Orford. Pp. 100. (London: Whittaker and Co., 1896.)

WHEN a book bearing the title "Modern Optical Instruments" is found to contain nothing about the telescope, merely a reference to the microscope, and but two pages on the spectroscope, it is the duty of a reviewer to declare that the volume is not what it pretends to be. The contents belong almost entirely to ophthalmoscopy; that is to say, to the determination of optical defects by means of the opthalmoscope, and the amelioration of them by means of spectacles. There are, in addition, brief chapters on stereoscopic projection and the optical lantern. As a short work on these matters, the book is not altogether bad (though the illustrations are very coarse), and opticians may find interest in parts of it. But to say the book is "a description of a few of what may safely be termed the more popular optical instruments in use," and to give it the title it has, is to court adverse criticism.

The book as published contains two-thirds text and one-third advertisement.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Cattle Plague in Africa.

THE following extract from a report addressed by Captain F. Lugard, C.B., managing director and leader of the expedition sent out by the British West Charterland to work its mining rights in Ngamiland, referring, as it does, to the outbreak of cattle disease which now paralyses transport throughout South Africa, may be of interest to the readers of NATURE.

There can now be little doubt that the present epidemic, known under the common name of "rinderpest," is the same as that with which we have been familiar in Central Africa for the past six years, and for the inroad of which into South Africa we ought long ago to have been prepared.

Commencing, so far as we know, in Somaliland in 1889, where the disease killed off a large part of the cattle, it passed through Masailand in the autumn of 1890. It was there that Captain Lugard, then an officer of the Imperial British East Africa Company, first came in contact with it. In 1891 he again found it sweeping off the cattle in the countries to the north and west of Uganda, of which province he was the Administrator. In 1892 it invaded North Nyasaland, and the Government were then duly warned of the double danger to be apprehended from the free export of hides of diseased animals, thousands of which were taken to America and to Europe, and through the advance of the epidemic into South Africa, should it cross the Zambesi and enter Bechuanaland.

The great peculiarity of the present disease is that it attacks not only domestic cattle, but also certain classes of wild animals, chiefly the buffalo, giraffe, warthog, the eland, and several other species of antelope. The elephant, the rhinoceros, and most of the smaller antelopes seem not to be affected, but in countries where it has appeared the destruction of cattle has been general.

The only accurate account of its previous ravages with which I am acquainted is to be found in Captain Lugard's work on "The Rise of our East African Empire," to which I would refer those who may wish to follow the course of the present epidemic from Somaliland South to Nyasaland.

Captain Lugard, writing from Gaberones, in Bechuanaland, May 13, says: "The results of the 'rinderpest' are here terribly *en évidence*. Near villages, literally hundreds and thousands of dead carcases lie about; they are found under almost every bush, and the stench is indescribable. I noticed that these carcases are being skinned by the natives, which means that the hides will be smuggled into the colony, and perhaps exported. I pointed this out yesterday to the magistrate here, and suggested that parties of police should burn the bodies in field cinerators, as fuel is abundant. He told me traders were buying up the hides, and he would recommend their confiscation and destruction by Government." He adds further on: "The magistrate told me that between here (Gaberones) and Buluwayo there are at least 4000 wagons stranded along the road (mostly loaded), of which the ox teams are dead. A famine threatens the country, for the ox is not only the food, but the money of the natives, with which they buy grain, &c. It is also their agricultural agent, for they no longer use the hoe; hence agriculture is at a standstill. The sole counterbalancing good is that it will compel the natives to work on the railway, which will now become a 'famine relief' work."

As little is known of the nature of the disease—some who have seen it in Central Africa classing it as a form of anthrax, others as a sort of pleuropneumonia—I annex an account of the chief symptoms as seen in the present epidemic in South Africa.

As regards the export of hides of diseased animals, to which Captain Lugard refers, which has gone on freely, and, to a large extent, from the Somali ports and from Zanzibar, I may remark that all hides before shipment are there dipped in a solution of arsenic and soda, which may, to a considerable extent, destroy any poisonous germs they contain.

The whole matter is now likely to be thoroughly worked out, but it cannot but be regretted that an inquiry was not instituted several years ago, when so many favourable opportunities of doing so were presented both on the Zanzibar coast and in Nyasaland.

JOHN KIRK.

Sevenoaks, June 10.

"*Zambesi Cattle Fever or Rinderpest.*

"This is a feverish disease of typical rapid course, which spreads by contagion and chiefly attacks cattle. Sheep, goats, and game are less liable; human beings, horses, mules, and donkeys do not get it. A healthy animal which has come into contact with a sick one usually shows the first symptoms of the disease seven days after; occasionally the period is considerably longer.

"General symptoms are fever, weariness, uneasiness, rough coat, failing appetite, increase of pulse and breathing, convulsive trembling of skin, rapid emaciation, and decline of strength.

"Special symptoms: One of the first and most constant is a frequent short cough, and thin slimy, afterwards mattery, discharge from the inflamed and swollen mucous membranes of the nose, eyes, and even mouth On the third (rarely so soon as the second) day diarrhœa sets in. The colour of the fæces depends upon the character and degree of the inflammation of the bowels. At the beginning they are still green, but quickly become discoloured. Some animals evacuate grey-brown, some a gelatine-like yellowish brown, and some clay-like fœtid excrement; the dark colour is due to the presence of blood. From the fourth or fifth day the fæces flow off involuntarily, and the anus appears red and swollen. Sometimes small ulcers and sores are visible on the mucous membrane of the lips, gums, and cheeks, and on those parts of the skin which can be licked.

"Diseased animals rarely succumb, earlier or later, than from the fourth to the seventh day after the first symptoms have become manifest.

"Experience has always shown that medical treatment is of no avail, but merely tends to spread the malady. It is therefore wisest and cheapest to destroy all animals affected at the earliest possible moment, and all carcases, unskinned and complete, should be burnt carefully or deeply buried.

"The disease does not originate through influences, such as cold and fog, dew or rain, but is solely due to a vegetable parasite, which is able to spread easily and rapidly.

(Signed) "OTTO HENNING,
"Government Veterinary Surgeon."

"The foregoing is published for general information. It is hoped that all will realise this great danger and the serious losses which the spread of the pest would produce, and that all will assist the authorities in extirpating it.

(Signed) "F. J. NEWTON,
"Resident Commissioner.

"Mafeking, March 16."

The Electrical Resistance of Alloys.

IN reference to Lord Rayleigh's very interesting note in your issue of June 18, we have, for several months, had preliminary experiments in progress, with the object of educing practical proof of the effects of thermo-electric currents upon the conductivity of alloys; but, owing to the stress of routine work in our respective departments, the research was not sufficiently advanced for publication. We had hoped, however, to be able to read a short note immediately after the long vacation.

About two years ago, one of us, who has been engaged in observing the microscopic structure of alloys, was first led to the conviction that the peculiar formation (so often met with) of metallic crystals enmeshed in a network of other metallic material must inevitably cause the production of thermo-electric currents when a current was passed through the alloy-mass. This, he believed, might account for the disproportionate effect of traces of impurities upon the conductivity of pure metals, and for the production of a curve (with percentages of impurity and electrical resistance as coordinates) which, steep at first, tended to become flatter as the percentage of impurity was increased. Prof. Dewar's experiments on the conductivity of pure metals, and of alloys at low temperatures, appeared to give additional proof of the correctness of this surmise, as Lord Rayleigh has pointed out. The pure metals, being perfectly homogeneous, may have no resistance at the absolute zero of temperature; but if other substances be added, so that there is produced the complex structure which the microscope shows the

mixture to possess, there would obviously be interference produced by the thermo-electric currents set up owing to the juxtaposition of these masses of unlike metals. It would be particularly interesting to observe whether pure entectic alloys or chemical compounds of metals, which alone appear to form really homogeneous masses of mixed metals, would behave like pure metals, or like other alloys in regard to conductivity at low temperatures.

In order to detect the presence of opposing E.M.F.s, we first tried the experiment of passing a fairly intense current through a bar of alloy, breaking contact by means of a simple switch, and immediately making connection with a galvanometer, the interval of time elapsing between the reversal of connections being but a small fraction of a second. We have hitherto, however, failed to obtain any indication in this manner, a fact which we ascribe to the rapidity with which the temperature of the mass is equalised, owing to the minute size of its constituent particles, and to the appreciable time that must elapse between the break of the current and the contact with the galvanometer. Even when the time was reduced to 1/100th of a second or less by the use of a Morse key, and when the process was repeated five times a second, no consistent indication of a residual E.M.F. could be detected with a D'Arsonval galvanometer giving a deflection of 0·5 mm. per micro-volt. The ordinary thermoelectric effects had of course to be eliminated, and were very troublesome.

The next experiment was to balance the resistance of two pieces of wire of equal diameter—one of copper, the other of alloy—against each other, using equal ratio arms on a Wheatstone bridge, and then by means of a secohmmeter to try if the resistance of the alloy diminished when the current was rapidly reversed. In all cases there was found to be a distinct reduction of the resistance of the alloy relatively to the copper, the above-mentioned galvanometer giving deflections of from 10 to 15 mm., with 60 reversals per second. In one case the alloy was copper = 75 per cent. : gold = 25 per cent., the wire being 0·7 mm. in diameter and 820 mm. long, whilst the copper wire was 0·7 mm. in diameter and 4100 mm. long ; the current used was about 1·5 amp., and the resistance of each wire was about 0·18 ohms. A deflection of 15 mm. on the galvanometer scale, corresponding to 30 micro-volts, would be caused by an unbalanced E.M.F. in one of the wire = 105 micro-volts, or, say, 1/2600th of the total E.M.F.

The time actually occupied in the reversal of the current was estimated as varying between 1/500th and 1/1000th of a second, which was the time available for equalisation of temperature before the current was started in the opposite direction. Any residual E.M.F. would then *assist* the current at "make," and so reduce the apparent resistance. In any case, at the first instant of starting the current, the opposing E.M.F. would be absent, but the time required for its appearance would be very small compared with the time between reversals (1/60th of a second). Increased effect should therefore be sought by increasing the number of reversals per second rather than by shortening the time between stopping and re-starting the current.

Care was, of course, taken to ensure equal capacities and inductances in each pair of arms of the bridge ; and an experiment was made to see if the observed effect was due to the current in the copper wire becoming concentrated near the surface. A copper wire 1000 mm. long and 0·35 mm. in diameter was balanced against another copper wire 4000 mm. long and 0·7 mm. in diameter ; but no variation of resistance was observed. At this point the investigation was allowed to rest, pending the construction of special apparatus and the arrival of the summer vacation.

Are Röntgen Rays Polarised?

MR. L. CASELLA has made for me a Crookes' tube having as the anode a platinum window sealed into the end of the tube opposite the kathode, which is the ordinary aluminium disc. Owing to the glass sealing, only a small portion of the platinum, about 3 mm. in diameter, is free to act. The light from all but this portion was screened off by thick glass discs and a brass disc, these having each an aperture in the centre. The result, with the fluorescent screen, was at first poor, because the vacuum was too low ; but as that got higher it improved, and I was able to electrograph a part of the hand, by the rays given off by this small platinum window, in 15 seconds, the plate being 2½" from the window. An ordinary focus tube takes 30 seconds to produce the same effect under similar conditions, but gives better definition. With the platinum window tube, though the bones are defined on the fluorescent screen, there seems to be too much white light, and the difference between bones and flesh is less marked. The tilted platinum of a focus tube, apparently, reflects most of the kathode rays, but transmits some. Compare the behaviour of the platinum in both tubes with the action of light on glass. With both glass and platinum, part of the rays are transmitted and part reflected, the proportion varying with the angle of incidence ; but, with both, those rays which are perpendicular are apparently transmitted. If the glass be tilted at the proper angle, the reflected rays and a small part of the transmitted rays are polarised. Suppose the plate of glass in the position of the platinum window, and the source of light a luminous point within the tube ; although most of the transmitted light would be radiated direct from the luminous point, part would be rays which had been polarised by reflection from the walls of the tube. The analogy would still hold good, for we know that, as far as X-rays are concerned, glass behaves very similarly to platinum, for these rays are under suitable conditions given off by both.

These considerations and the appearance of microscopic preparations containing bone undecalcified when examined by low powers and ordinary light under Nicol prisms, lead me to hazard the suggestion that a bare possibility exists of X-rays being polarised kathode rays. Were this so, the two kinds of X-ray described by several observers would be explained, and we should also understand why those who have tried to polarise these X-rays should have failed, the rays being already polarised. If this view is correct, extinction of the X-rays should be caused by reflection from a second platinum surface at the proper angle. Whether this would succeed at atmospheric pressure, I know not ; the experiment should be tried in vacuo, and a tube constructed specially for the purpose. The window tube has, at all events, proved that a quantity of kathode rays, with some X-rays, may be transmitted through moderately thin platinum under these conditions.

Chard, June 9.

A Curious Bird's Nest.

A CURIOUS bird's nest, or rather its adjuncts, has lately been presented to the Warwick Museum. It was found in a curved iron pipe intended to deliver water from a well at the baths, and appears not to have been used for some time. The entire length of the pipe was four feet, and the diameter five inches. The bird had built its nest in the centre, and had not only surrounded it with moss and other materials, but had extended them for some length on each side, the total amounting to two feet two inches. The singular thing is that the bird should have taken so much trouble to do this, and it really might seem as if, like the bower birds, it had done it in sport ; for it was not necessary (though the sharp little bird may have thought so) for the preservation of the nest to extend it so far on each side with moss, feathers, and other things. The eight small eggs in the nest appear to have belonged to the blue titmouse.

"Hydrodictyon reticulatum."

IT may interest readers of NATURE who collect fresh-water Algæ, to know how easy of cultivation is this beautiful species It occurs frequently, though by no means every year, in one of the tanks in the Royal Gardens, Kew. Last summer, about this time, I gathered it there in considerable quantities. After preparing specimens for demonstration, I placed the remainder in a glass dish, where it remained in my study, entirely neglected, except for an occasional renewal of the water, until a week or two ago, when I found it still in beautiful condition, with both large and small nets. It is to be found again this year in its original habitat, with nets of an unusually large, almost gigantic, size.

London, June 20.

"The Old Light and the New."

YOUR reviewer expressed an opinion, and makes two statements, and the six lines comprise his review of my book. The opinion, being on a matter of business, may be right or may be wrong. The statements are supposed to relate to fact; but they must be the outcome of hasty reading, for the "large portion of the book, dealing with theories of the natural colours of bodies," cannot surely be spoken of as "padding" in a work whose sub-title is "The Chemistry of Colour," and one of whose objects is to show that the Röntgen rays and matter yield "invisible" colour which conforms to the same laws as "visible" colour. Nor do I think it correct to call information on the X-rays "sketchy" because it happens to be concise.

WILLIAM ACKROYD.

IN my brief criticism of Mr. Ackroyd's book, I did not intend to suggest that the *whole* of the section on natural colours was "padding." My meaning would, perhaps, have been clearer had I written, "a large portion of that part of the book which deals with theories of the natural colour of bodies is nothing more than padding." The forty pages which comprise the chapter on "The Chemistry of Colour," contain the substance of a lecture delivered before the Society of Dyers and Colourists, and is so full of tabular details, while the remainder of the book is of a very elementary character, that it certainly gives the impression of having been included more to increase the bulk than on account of suitability.

YOUR REVIEWER.

"The Reminiscences of a Yorkshire Naturalist."

THE brevity of the reference, on page 205 of "The Reminiscences of a Yorkshire Naturalist," by Dr. W. C. Williamson, to the memoir in the *Annales des Sciences Naturelles*, may give rise to misconception. Prof. Hartog's share in this work was by no means that of a mere translator, although his exceptional ability as a French scholar was of essential service. His collaboration extended to the substance as well as the form of the memoir, and he was always fully recognised by Dr. Williamson as its joint author.

A. C. WILLIAMSON.

Post-Graduate Study in London.

COULD you inform a graduate in science of London University whether there is any place in London where he could attend post-graduate and research courses of study in botany? He is engaged as science master in a large public day-school, but is anxious to study botany in his spare time. Any information will greatly oblige.

"PUTHOS."

June 14.

LORD KELVIN'S JUBILEE.

OUR summary in last week's issue of the proceedings at Lord Kelvin's jubilee celebration gives only a faint idea of the completeness and success with which every part of the festival was carried out, or of the enthusiasm which characterised what was the world's tribute of admiration to the achievements and personal qualities of a truly great man. The list of delegates and visitors which we give on pp. 174–5 will convey some idea of the unanimity with which science and learning throughout the world have done honour to one who, besides advancing pure science in a remarkable degree by his own abstract researches, has not disdained to apply his great knowledge of scientific principles to the construction of apparatus and appliances which have promoted peace and good will among men and aided commerce by placing continents in telegraphic communication, by improving and facilitating navigation, and last but not least, diminished the perils to which those who sail the seas are exposed. A great physical mathematician, a physicist to whom physical principles are intuitive, an engineer whom engineers have united to honour as one of the greatest of themselves, Lord Kelvin has many scientific interests, and there is no department of science which is not the larger and richer for his work.

The opening meeting of the celebration was the conversazione on Monday evening at the University. The guests were received by the Senatus Academicus, and the members of the Corporation of the City of Glasgow headed by Lord Provost Sir James Bell, in the Randolph Hall, which forms a "Fore Hall" or vestibule for the magnificent Bute Hall in which the high ceremonies of the University are held. In the Bute Hall, a little beyond the entrance and to the left, chairs were set for Lord and Lady Kelvin, who stood receiving the individual congratulations of the multitude of distinguished visitors. After thus paying their respects to the hero of the occasion, the guests passed on to meet one another, to renew acquaintanceships, to look at the treasures of the museum, and to inspect the splendid collection of instruments, diplomas, and medals which had been arranged to illustrate Lord Kelvin's researches and inventions, and the honours he has received. In this exhibition were many things of great interest, and we will not attempt even their enumeration. To give an adequate account of the instruments alone would require several numbers of NATURE, while the diplomas, mostly in Latin and of extraordinary distinction, represented the honour in which Lord Kelvin is held by the learned societies at home and abroad. Beginning with the certificate of the Bishop of Ely approving the appointment of William Thomson, B.A., as a Fellow of Peterhouse, they ended with the credentials of Sir William Thomson or Lord Kelvin's election as member of every one of the most distinguished scientific societies of the world, and included the letters of the Perpetual Secretary announcing, first, Lord Kelvin's election as Corresponding Member, next, as Foreign Associate of the Institute of France, and the announcement of his appointment as *Grand Officier* of the Legion of Honour.

The part played by the telegraph in the conversazione formed an exceedingly interesting part of the proceedings. The chief Cable Companies—the Anglo-American, the Commercial, the Eastern, and the Brazilian Submarine—sent congratulations, and instruments were arranged in the Library Hall whereby messages could be received from all parts of the world during the soirée. The Anglo-American Company's message may here be quoted, as it gives in a few words that credit for rendering by his instruments submarine telegraphy practically possible, which is Lord Kelvin's due, and that by a large portion of the commercial public that carries on business by means of cable communication is either unknown or apparently forgotten.

In 1858 Professor William Thomson took out his first patent for a system of working long cables, and for instruments (including the mirror-galvanometer) calculated for producing a high rate of transmission. In the Atlantic expedition of 1858 Professor William Thomson, at that time one of the directors of the Atlantic Telegraph Co., at the request of his brother directors, took upon himself the duties of electrician on board H.M.S. *Agamemnon*, which had been placed at the disposal of the company for the laying of the first Atlantic cable; and when the cable had been laid, it was Professor William Thomson's inventions and genius which caused a sufficient number of messages to be transmitted to demonstrate the practicability of Atlantic telegraphy, thus contributing most materially to the present success.

Our readers will remember that the theoretical solution of the problem of telegraph signalling by Lord Kelvin consisted in showing that the "retardation" of a signal increases in direct proportion to the square of the length of the cable supposed of a given pattern; and that therefore it was only possible by using receiving instruments far surpassing in delicacy the most sensitive of land instruments that intelligible signals could be obtained at all. There can be no manner of doubt that it was the tremendous battery power used to actuate the primitive receiving instruments that ruined the cable first laid, and brought temporary disaster to the promoters. The mirror-galvanometer with its needle and mirror of a grain or two hung by a single fibre of silk, and its long mass-

less index of a ray of light, first overcame the difficulty and reduced the battery power required to something like a fiftieth or a hundredth part of that originally employed. Then came the beautiful siphon-recorder with its pen of lightest capillary tubing, through which the ink was forced by electrical action, so that it wrote its message on a ribbon of paper without actually touching the paper-surface, thus avoiding in the most ingeniously simple manner what for long-cable signalling would have been most detrimental, the friction of the glass on the ribbon. The recorder-siphon once deflected registered successive signals in the same direction by small ripples drawn on the moving paper as from a new zero, and thus the reduction to zero between two of these signals of the current deflecting the coil, was rendered unnecessary. The shifting zero of the siphon-recorder was made still more definite in whatever position it took up by means of curb-sending, which brought out clearly the individual ripples of the last three signals of the letter *b*, the four successive signals in the same direction which form the letter *h*, and so on.

Returning, however, to the conversazione and the part played by the telegraphic instruments, we have first to mention the message of congratulation which was sent by the Jubilee Committee to Lord Kelvin, present in the same room, round a circuit as long as about three-quarters of the earth's circumference. The Anglo-American Company sent the message to Heart's Content, thence to New York, thence round by Chicago and San Francisco back to New York, thence again to Heart's Content and Glasgow. The message was as follows :—

By the Atlantic cable which represents your unrivalled combination of scientific genius and practical skill, the Glasgow Jubilee Committee send you their warmest congratulations.

The interval between sending and receiving was seven and a half minutes, and Lord Kelvin replied :—

The Cable Companies have beaten Ariel by half a minute. Warmest thanks to the Glasgow University Jubilee Committee.

The reply took only four minutes.

From Simla the Viceroy of India telegraphed :—

I offer congratulations and desire to join with the University of Glasgow in celebrating your fifty years of service. We in India, thanks to your labours, constantly feel closer to friends at home.

From the capital of the Orange Free State the following message was received :—

The President of the Orange Free State, in the name of many Free Staters who have either directly or indirectly profited by Lord Kelvin's magnificent services to science, desires to offer his hearty congratulations to Lord Kelvin on the celebration of his professorial jubilee.

Congratulatory telegrams were also received from Earl Grey (Buluwayo), Sir James Sievewright (Cape Colony), the Earl of Glasgow (Wellington, New Zealand), the Postmaster-General of New Zealand, Sir John Robinson (Prime Minister of Natal), the Governor of Hong Kong, Lord Hampden (Sydney), the Universities of Adelaide, Madras, New Zealand, Calcutta, Santiago, the Johns Hopkins University of Baltimore, and Chicago, from the Indian Telegraph Department, the College of Science, Poona, and old students and friends in Japan, and almost all parts of the world.

Lord Kelvin telegraphed his thanks to General Eckert, the President of the Western Union Telegraph Company, New York, in the following terms :—

Pray accept my sincere thanks to yourself and staff for your great kindness and assistance. The messages you have transmitted to me have given very great pleasure to the whole assembly.

The following is a list of the delegates and other distinguished visitors who, besides the Lord Provost, Magistrates, and Town Council, the members of the Senatus Academicus, and the local guests invited, were announced as present at the reception and throughout the celebration :—

REPRESENTATIVES OF UNIVERSITIES, SOCIETIES, INSTITUTIONS, &c.

Austro-Hungary.—Prof. Dr. Izidor Fröhlich, Academy of Sciences, Buda-Pest.

Belgium.—Senator Montefiore Levi, of Brussels.

Denmark.—Prof. C. Christiansen, Royal Danish Society of Science, Copenhagen.

France.—Prof. Aug. Angellier, Academy of Lille; Prof. Pinloche, Academy of Lille; Prof. Lippmann, University of France, Paris; Prof. Henri Moissan, University of France, Paris; Prof. Picard, University of France, Paris; Prof. Bonet Maury, University of Paris; Prof. Eleuthère Mascart, Collège de France, Paris; Prof. Violle, Ecole Normale Supérieure, Paris.

Germany.—Prof. Heinrich du Bois, University of Berlin; Prof. Georg Quincke, University of Heidelberg; Prof. Woldemar Voigt, Royal Society of Science, Göttingen.

Holland.—Dr. Elie van Rijckevorrel, Batavian Society of Experimental Philosophy, Rotterdam.

Italy.—General Annibale Ferrero, Italian Ambassador, London, representing Royal Institute of Science and Letters, Milan; Royal Academy of Science, Letters, and Arts, Modena; Italian Society of Science, Rome. Prof. Peter G. Tait, M.A., D.Sc., Edinburgh, representing University of Rome. Prof. J. J. Thomson, M.A., F.R.S., Cambridge, representing Royal Academy of Turin.

Mexico.—George J. Symons, F.R.S., representing the Antonio Alzate, Scientific Society.

Russia.—Prof. Nicholas Oumov, representing University of Moscow; Imperial Society of Friends of Natural Science, Anthropology, and Ethnography, Moscow; and Imperial Society of Naturalists, Moscow.

Sweden.—Prof. Per Theodor Cleve, University of Upsala.

Switzerland.—Mons. Lucien de Candolle, Société des Arts, Geneva.

United States of America.—Prof. Joseph S. Ames, Ph.D., Johns Hopkins University, Baltimore; James C. Thomas, M.D., Johns Hopkins University, Baltimore; Prof. Cushney, University of Michigan; Prof. Robert M. Wenley, M.A., D.Phil., University of Michigan; Prof. G. F. Barker, M.D., University of Pennsylvania, Philadelphia; Mr. Samuel Dickson, University of Pennsylvania, Philadelphia; Prof. Woodrow Wilson, Princeton University, New Jersey; Prof. Van Amringe, Columbia College, New York; Mr. T. C. Martin, National Electric Light Association, New York; Right Hon. Lord Rayleigh, F.R.S., representing American Academy of Arts and Sciences, Boston; General Wistar, Academy of Natural Sciences, Philadelphia; Dr. J. Cheston Morris, Philosophical Society, Philadelphia.

GREAT BRITAIN AND IRELAND, THE COLONIES, AND INDIA.

Canada.—Sir D. A. Smith, K.C.M.G., LL.D., M'Gill University, Montreal; Principal Peterson, M'Gill University, Montreal; Mr. James Ross, Canadian Society of Civil Engineers, Montreal.

India.—Mr. Justice Jardine, I.C.S., Bombay University; Ghanasham N. Nadkarin, LL.B., Bombay University; Prof. J. H. Gilliland, M.A., Calcutta University.

New South Wales.—Prof. Liversidge, M.A., F.R.S., University of Sydney.

UNITED KINGDOM.

I. Universities.

ENGLAND.

Cambridge University.—Prof. A. R. Forsyth, D.Sc., F.R.S.; Prof. Sir George G. Stokes, LL.D., F.R.S.; Prof. J. J. Thomson, M.A., F.R.S.

Durham University.—Rev. Principal Gurney, D.C.L.; Dr. Merz.

London University.—Prof. Carey Foster, F.R.S.; Sir Henry E. Roscoe, F.R.S.

Manchester—Victoria University.—Prof. Oliver J. Lodge, D.Sc., F.R.S.; Principal A. W. Ward, Litt.D., LL.D.

Oxford University.—Prof. Clifton, F.R.S.; D. B. Monro, M.A.; Provost of Oriel College; Prof. Burdon Sanderson, F.R.S.

IRELAND.

Dublin—Trinity College.—Right Hon. the Earl of Rosse, LL.D., D.C.L., F.R.S. Chancellor of the University of Dublin.

Royal University of Ireland.—Right Rev. Monsignor Molloy, D.D., D.Sc.; William A. M'Keown, M.D.

SCOTLAND.

Aberdeen University.—Prof. Finlay, M.D.; Prof. Niven, F.R.S.; Prof. Pirie.

Edinburgh University.—Prof. A. Crum Brown, F.R.S.; Prof. Sir William Turner, F.R.S.; Prof. Peter G. Tait, M.A., D.Sc.

St. Andrew's University.—Prof. Scott Lang; Prof. Pettigrew, M.D., LL.D., F.R.S.

WALES.

University of Wales.—Prof. Andrew Gray, LL.D. F.R.S.; Principal J. Viriamu Jones, F.R.S., Vice-Chancellor of the University of Wales.

II.—COLLEGES.

ENGLAND.

Birmingham—Mason College.—Principal Heath, D.Sc., F.R.S.

Leeds—Yorkshire College.—Prof. Stroud, D.Sc.

Liverpool—University College.—Prof. M'Cunn, M.A.

London—King's College.—Prof. W. G. Adams, D.Sc., F.R.S.

London—University College.—Prof. Ramsay, F.R.S.

London—City and Guilds Central Technical College.—Prof. W. E. Ayrton, F.R.S.

London—City and Guilds Technical College, Finsbury.—Prof. S. P. Thompson, D.Sc., F.R.S.

Manchester—Owens College.—Prof. Osborne Reynolds, LL.D., F.R.S.

Newcastle-on-Tyne—Durham College of Medicine and Science.—Prof. George H. Philipson, M.D.

IRELAND.

Belfast—Queen's College.—Rev. Thomas Hamilton, D.D., LL.D.; Prof. Purser, LL.D.

Cork—Queen's College.—Prof. W. Bergin, M.A.

Galway—Queen's College.—Sir Thomas Moffett, LL.D.

SCOTLAND.

Dundee.—University College.—Prof. Steggall, M.A.

Glasgow—Faculty of Physicians and Surgeons.—Bruce Goff, M.D., F.F.P.S.

Glasgow and West of Scotland Technical College.—Henry Dyer, D.Sc.

Glasgow School Board.—Sir John N. Cuthbertson, LL.D.; Rev. William Boyd, LL.D.

WALES.

Aberystwith—University College.—R. D. Roberts, M.A., D.Sc.

Bangor—University College.—Prof. Andrew Gray, LL.D., F.R.S.

Cardiff—University College.—Prof. A. C. Elliott, D.Sc.

III.—SOCIETIES, INSTITUTIONS, &c.

ENGLAND.

Royal Society.—Prof. Sir Joseph Lister, M.B., P.R.S.; Sir John Evans, K.C.B., F.R.S.

Cambridge—Philosophical Society.—Prof. J. J. Thomson, F.R.S.

London—Society of Arts.—Sir Frederick Abel, F.R.S.

Astronomical Society.—A. A. Common, LL.D., F.R.S.

British Association for Advancement of Science.—Prof. A. W. Rücker, F.R.S.

Chemical Society.—Prof. John M. Thomson.

Institution of Civil Engineers.—Sir Benjamin Baker, F.R.S., K.C.M.G.

Society of Engineers.—Henry O'Connor.

Institution of Electrical Engineers.—John Hopkinson, F.R.S.

Royal Geographical Society.—Dr. John Murray, F.R.S.

Geological Society.—Dr. Henry Hicks, F.R.S.

Mathematical Society.—Major P. A. MacMahon, R.A., F.R.S.

Physical Society.—Captain W. de W. Abney, F.R.S.

Manchester Literary and Philosophical Society.—Prof. Schuster, F.R.S.

IRELAND.

Royal Irish Academy.—Right Hon. the Earl of Rosse, LL.D., D.C.L., F.R.S.

SCOTLAND.

Edinburgh—Educational Institute of Scotland.—John Dunlop, Esq.

Edinburgh—Royal Society.—Hon. Lord M'Laren.

Glasgow—Geological Society.—Sir Archibald Geikie, LL.D. F.R.S.; J. Barclay Murdoch, Esq.

Glasgow—Institution of Engineers and Shipbuilders.—John Inglis, Esq.

Glasgow—Philosophical Society.—Ebenezer Duncan, M.D.

Other distinguished Visitors.—Professor Cleveland Abbe, Weather Bureau, Washington; John Aitken, F.R.S., Darroch, Falkirk; Prof. Roberts-Austen, C.B., F.R.S., London; Prof. Bayley Balfour, M.D., F.R.S., Edinburgh University; Rev. A. K. H. Boyd, D.D., St. Andrews; A. Hargreaves Brown, M.P., 12 Grosvenor Gardens, London, S.W.; Alexander Buchan, LL.D., 42 Heriot Row, Edinburgh; Professor G. H. Darwin, LL.D., F.R.S., Newnham Grange, Cambridge; Prof. James Dewar, LL.D., F.R.S., Peterhouse, Cambridge; Lowes Dickenson, Esq., 1 All Souls' Place, London, W.; J. D. H. Dickson, M.A., Peterhouse, Cambridge; John M. Dodds, M.A., Peterhouse, Cambridge; Prof. J. A. Ewing, LL.D., F.R.S., Cambridge; Prof. Fitzgerald, Sc.D., Dublin; J. E. Foster, M.A., Cambridge; Prof. Michael Foster, LL.D., F.R.S., Cambridge; Prof. Frankland, F.R.S., Mason College, Birmingham; Ex-Prof. Frederick Fuller, London; David Gill, C.B., LL.D., F.R.S., Astronomer Royal, Cape Town; Dr. Gladstone, F.R.S., London; J. G. Gordon, Esq., London; Prof. Herkomer, R.A., Bushey, Herts.; Sir Joseph D. Hooker, M.D., K.C.B., F.R.S., Sunningdale, Berks; John K. Ingram, LL.D., Dublin; Prof. Alex. B. W. Kennedy, LL.D., F.R.S., London; Hon. Lord Kinnear; Hon. Lord Kyllachy; Count Lovatelli, Italian Embassy, London; Rt. Hon. Prof. Max Müller, LL.D., Oxford; Frank M'Clean, LL.D., F.R.S., Tunbridge Wells; John M'Intyre, M.D., Odiham, Hants; Prof. Simon Newcomb, of Johns Hopkins University, Baltimore, and Nautical Almanac Office, Washington; Prof. Perry, F.R.S., London; Rev. Dr. Porter, Master of Peterhouse, Cambridge; W. H. Preece, C.B., F.R.S., General Post Office, London; Emanuel Ristori, London; Edward J. Routh, D.Sc., LL.D., F.R.S., Peterhouse, Cambridge; Sir William Russell, Adare, Ireland; Right. Hon. Lord Shand, LL.D., London; Alex. Siemens, London; Major-General Sir R. M. Smith, K.C.M.G., Edinburgh; Prof, J. J. Sylvester, M.A., D.C.L., F.R.S., Oxford; James Thomson, M.A., C.E., Newcastle-on-Tyne; Prof. W. A. Tilden, Sc.D., F.R.S., London; Admiral Wharton, R.N., C.B., F.R.S., Admiralty, London.

The only noticeable want in the above list is that of any high Officer of State of our own country. The presence of some member of the Government would have added a touch of State official recognition which it would have done honour to the Government to bestow; but very possibly, like Lord Salisbury and Sir John Gorst, other ministers were unable to leave their posts.

The suite of rooms, unique in extent and convenience for such an assembly, beautiful in themselves because of their architecture and fittings, were further decorated with flowers and plants, and were illuminated by several arc-lamps which shed a bright but mellow light upon the scene. The effect was indescribably brilliant—the splendour of the ladies' dresses, the uniforms, and the municipal and academic robes of the men, mixed with the sober evening attire to which many adhered, rendered the appearance of the rooms during the evening exceedingly picturesque and bright. The east quadrangle was also lighted with the electric light, and formed a most attractive refuge from the hotter atmosphere inside. The band of the Gordon Highlanders discoursed sweet music at intervals from a band stand erected in the centre of the quadrangle, alternating with the pipers of the same regiment, who played a selection of Highland airs in excellent style.

On Tuesday a congregation of the University was held for the presentation of addresses to Lord Kelvin, and the conferring of honorary degrees on Lord Kelvin himself and the principal foreign visitors representative of science. The delegates of the various universities, colleges, societies, and institutions were accommodated

with seats in front of the principal floor-space of the hall, while the chair of the Vice-Chancellor, with chairs for officials, was placed in the centre of a semicircle of professional stalls occupied by the members of the Senatus Academicus, distinguished strangers, and representatives of the Corporation present. For the delegates who were to receive degrees, chairs were set in front of the circle occupied by the Senate. The rest of the hall and the galleries were occupied by students and spectators.

Punctually at 10 a.m. the Senatus with Lord Kelvin at its head, marched in procession up the hall, while the whole assemblage rose and cheered him to the echo. In the absence of Principal Caird, who unfortunately is not yet sufficiently recovered in health to take part in such a ceremony, the chair was taken by Prof. William Gairdner, F.R.S., who, next to Lord Kelvin, is the senior Professor now at Glasgow. After prayer, offered in Latin according to a form which has been long in use at Glasgow, Professor Stewart, Clerk of Senate, read the following letter of congratulation from H.R.H. the Prince of Wales.

Marlborough House,
Pall Mall, S.W.,
June 10, 1896.

Dear Lord Kelvin,—The Prince of Wales desires me to offer you his warmest congratulations upon your having attained the fiftieth year of the tenure of your professorship in the University of Glasgow.

His Royal Highness is in most cordial sympathy with the eminent representatives of universities, learned societies, and other public bodies in different parts of this Empire and in foreign States who, to do you honour, have assembled in the University which has for a long series of years, eventful through the rapid advance of science and its applications, enjoyed the high prestige derived from your close association with its work, and from the invaluable and brilliant contributions to science resulting from the researches carried on by you during the last half-century within its walls.

The Prince of Wales remembers with much satisfaction that he had the gratification seventeen years ago to present you with the medal instituted by the Society of Arts as a memorial of the Prince Consort, and awarded to men who have rendered pre-eminent service in promoting arts, manufactures, and science.

The work which you had at that time accomplished was but an earnest of the important researches to which you have since then devoted yourself so indefatigably, and he cherishes the sincere hope that you may long continue to enjoy the happiness derived from the most gratifying evidence that the high value of the services rendered by you through science to mankind is universally recognised and appreciated.

I remain,
Dear Lord Kelvin,
Yours truly,
Francis Knollys.

P.S.—His Royal Highness desires me to repeat what he has already stated to the University authorities, how greatly he regrets that long-formed engagements in the South prevent him from having the pleasure of being present on the occasion of this interesting celebration.—F. K.

Professor Story then called forward the delegates very nearly in the order in which they are given in the foregoing list. These advanced to the daïs, and presented the messages with which they were charged to Lord Kelvin; and after shaking hands with him, retired to their places. Most of the delegates presented elaborate addresses, beautifully engrossed, and signed by the authorities of the bodies represented. These were not, however, in general read, though a good many delegates made a few pointed remarks when placing the addresses before Lord Kelvin on the table. The delegates of the Institute of France were the bearers to Lord Kelvin of the Arago medal, which has only been three times before bestowed on any one. It is interesting to note in this connection that the Freedom of the City of Glasgow was in 1834 conferred on Arago himself "in testimony of admiration of his high talents and eminent scientific attainments, and particularly of his successful exertions to extend the boundaries of astronomical science."

The medal was presented to Lord Kelvin by Professor E. Mascart, of the Collège de France.

General Ferrero, the Italian Ambassador, attended on behalf of the Royal Institute of Science and Letters of Milan, the Royal Academy of Science, Letters, and Arts of Modena, and the Italian Society of Science, Rome.

The presentation of the addresses of the Royal Society, the University of Cambridge, the students of the four Scottish Universities, the students of the University of Glasgow, and the Senatus of the University of Glasgow excited much interest.

The address of the University of Cambridge, written by the Public Orator, Dr. Sandys, on behalf of the University, was as follows:—

Baroni Kelvin
Regiae Societatis nuper Praesidi
Philosophiae Naturalis inter Glasguenses
per annos quinquaginta Professori
S. P. D.
Universitas Cantabrigiensis.

Dum tot tantaeque Universitates praeceptori tam illustri annos quinquaginta Professoris in munere feliciter exactos certatim gratulantur, Universitati nostrae imprimis consentaneum est ob rem tam laetam tamque honorificam suum gaudium confiteri, suam superbiam testificari. Etenim nostra inter nemora (iuvat recordari) quinquagesimo primo abhinc anno studiorum mathematicorum e certamine primo lauream prope primam reportasti, studiorum eorundem in certamine altero victor renuntiatus. Nostris umbraculis egressus, et alios ex aliis honores serie perpetua propter insignia merita adeptus, physicorum praesertim studiorum provinciam et inventis tuis et exemplo tuo praeclare illustrasti. Tu trans maria magna navigantibus securitatem novam dedisti, septentrionum regionem accuratius indicasti, vada periculosa etiam in ipso transcursu metiri docuisti; tu oceani denique Atlantici litus utrumque vinculo novo coniunxisti. Haec et alia inventa egregia dum contemplamur, non sine superbia recordamur plusquam quinquaginta per annos ipsum inventorem etiam nostra cum Universitate vinculo artissimo fuisse coniunctum. Alumno igitur nostro insigni, non modo annos quinquaginta Professoris in munere prospere peractos, sed etiam vitae annum septuagesimum primum feliciter expletum libenter gratulati, etiam in posterum plurimos per annos omnia fausta ex animo exoptamus. Vale.

Datum Cantabrigiae
mensis Iunii die xi°
A. S. MDCCCXCVI.

L. S.

The following address of the Senatus of the University of Glasgow was read by Professor Stewart, D.D.:—

My Lord,—The rejoicings which have been arranged to celebrate the close of your fiftieth session betoken the admiration and affection with which you are regarded by your colleagues in the Senate, but it is none the less fitting that on this auspicious occasion these feelings should find articulate expression in an address of congratulation. The fifty years during which you have occupied the Chair of Natural Philosophy in this University have to an extent, unparalleled in the history of the world, been marked by brilliant discoveries in every department of physical science, and by the prompt adaptation of many of these discoveries to meet the practical needs of mankind. We recognise with admiration that in both these respects you have been a leader of the age in which we live. Your mathematical and experimental genius has unveiled the secrets of nature; your marvellous gift of utilising such discoveries has ministered in many ways to the happiness and dignity of human life. Your name and your work have been an inspiration to the physicists of the world; new departments of technical industry have sprung into existence under your hand, and even the unlettered have learned to value the gifts which science bestows. The justice of the tributes which have been paid to you by universities and scientific societies at home and abroad, and by the Governments of this and other lands, we are proud to acknowledge. But only your colleagues in university work are in a position to

appreciate the versatility of faculty, the exhaustless energy, and the tenacity of purpose which have enabled you to grapple successfully with problems the most varied, and to reveal to us on every side the reign of order and law. In the midst of all you have endeared yourself to us by the graces of your personal character, notably by that simplicity which, unmarred by honours or success, remains the permanent possession of transcendent genius, and by that humility of spirit which, the clearer the vision of truth becomes, bows with the lowlier reverence before the mystery of the universe.

My Lord, the contemplation of a past so rich in achievements and honours encourages your colleagues to look forward to the future in the hope that you may have health and strength to win new triumphs in years to come, and long to remain among us the ornament and the glory of our ancient University.

William Stewart.
Clerk of Session.

The address from the Royal Society was presented by the President, Sir Joseph Lister, Bart., and the Treasurer, Sir John Evans, K.C.B. It ran as follows :—

The Royal Society.

Dear Lord Kelvin,—The President, Council, and Fellows of the Royal Society desire, on the happy occasion of the jubilee of your Professoriate in the University of Glasgow, not only to be represented, as they are, by their highest officers, the President and Treasurer, but also to assure you, by some direct words, of the warm sympathy of the whole Society.

There is no need to dwell on the many ways in which you have contributed to that improvement of natural knowledge to secure which the Society was founded, or on the many valuable communications with which you have enriched the Society's records. Since you first joined the Society, and the jubilee of that event is not far off, the Society has always known how much your belonging to it has added to its strength ; but it has been especially during the recent five years, which went too swiftly by, while you filled in so admirable a manner the chair of President, that the Society has felt how close are the ties which bind it to you and you to it.

We ask you to receive our heartiest congratulations on the present glad event, and our warmest wishes for your welfare in the years yet to come.

(Signed) Joseph Lister, Pres. R.S.

When the presentation of addresses had been completed, Professor Moody Stuart, Dean of the Faculty of Law, amid great and prolonged applause presented Lord Kelvin for the degree of Doctor of Laws. "As a memorial," he said, "of this day, the Senate desire to confer on Lord Kelvin the highest honour they have to bestow, by placing his illustrious name on the roll of Doctors of Laws of the University."

The ceremony of capping was performed by Professor Gairdner, amid a renewed outburst of cheering.

Lord Kelvin thereafter took the chair as Senior Professor in the University, and proceeded to confer the remainder of the honorary degrees.

Prof. Moody Stuart, in presenting the recipients, said :— The Senate desire to commemorate this occasion by conferring the honorary degree of Doctor of Laws on some of the distinguished men of science from the continent of Europe, from the United States of America, and from the British Colonies, who have honoured the University by their presence to-day. In the name of the Faculty of Law, and by authority of the Senate, I have now the honour of presenting them for this degree.

Prof. Cleveland Abbe, head of the Meteorological Office, Washington, distinguished for his important contributions to astronomical and meteorological science.

Prof. Christian Christiansen, Copenhagen, author of many important papers on physical science, and of a most beautiful experimental illustration of differences of refractivity at different temperatures.

Prof. Per Theodore Cleve, of Upsala, long esteemed as one of the most notable workers in chemical and mineralogical science. His name has become known to a wider public in connection with the discovery of helium in the mineral Cleveite named after him.

His Excellency General Annibale Ferrero, Ambassador to this country from His Majesty the King of Italy. General Ferrero is specially eminent in mathematical and geodetical science, and, notwithstanding the engrossing duties of his high office, continues to take his part in the scientific work to which his life has been devoted.

Prof. Izidor Fröhlich, of the University of Buda-Pesth and Academy of Sciences, Buda-Pesth, who has published a large number of important papers on physical optics and on electricity.

Prof. Gabriel Lippmann, of the Sorbonne, Paris, inventor of the capillary electrometer and discoverer of the principles of true colour photography.

Prof. Archibald Liversidge, of the University of Sydney, New South Wales, Dean of Faculties in that university, distinguished as a traveller, a chemist, and a geologist.

Prof. Eleuthère Mascart, official head of meteorology in France, a physicist of great reputation, and author of a very important treatise on electricity.

Prof. Henri Moissan, of the University of France, one of the most originative and practical of modern chemists.

Prof. Simon Newcomb, of Johns Hopkins University, Baltimore, whose numerous researches have contributed largely to the progress of gravitational astronomy, the most notable being his work on the satellites of Saturn and his researches on the motion of the moon. He was awarded the Copley Medal of the Royal Society of London in 1890.

Prof. Nikolai Aleksejevich Oumov, of the University of Moscow, who has gained great distinction by his researches on energy and on electro-dynamic induction.

Prof. Émile Picard, of the University of France, who holds a leading position among the great French mathematicians.

Prof. Georg Quincke, of the University of Heidelberg, one of the most famous experimental physicists in Germany, author of numerous important experimental investigations, among others on capillarity and in optics.

Prof. Woldemar Voigt, of the University of Göttingen, well known as the author of numerous papers on the mathematical theory of light and on the electricity of crystals.

Lord Kelvin then said—The University of Glasgow is honoured by the presence to-day of many distinguished visitors from foreign countries, from America, from India, from Australia, and from all parts of the United Kingdom. Names of men renowned for their scientific work in distant countries have been added to our list of honorary graduates. That I have had the honour of conferring these degrees in the name of the University is a subject of keenest regret to all here present, because it is due to the absence of Principal Caird on account of illness. We hope that the beginning of next session will see him at home in the University with thoroughly recovered health. In his absence the duty of conferring degrees has fallen, according to University law, on me as senior Professor present. I am also one of the recipients of the degree, and, in the name of all who have to-day been created Doctors of Laws of the University of Glasgow, I thank the Senate for the honour which we have thus received on the occasion of the jubilee of my professorship. For myself, I can find no words to express my feelings on this occasion. My fifty happy years of life and work as Professor of Natural Philosophy here, among my students and my colleagues of the University and my many kind friends in the great City of Glasgow, call for gratitude ; I cannot think of them without heartfelt gratitude. But now you heap coals of fire on my head. You reward me for having enjoyed for fifty years the privilege of spending my time in the work most congenial to me and in the happiest of surroundings. You could not do more for me if I had spent my life in hardships and dangers, fighting for my country, or struggling to do good among the masses of our population, or working for the benefit of the people in public duty voluntarily accepted. I have had the honour to receive here to-day a gracious message from His Royal Highness the Prince of Wales, and addresses from sister-universities in all parts of the world ; from learned societies, academies, associations, and institutions for the advancement of pure and applied science ; from municipal corporations and other public bodies ; from submarine telegraph companies, and from their officers, my old comrades in their work ; from students, professors, and scientific workers of England, Scotland, and Ireland and other countries, including my revered and loved St. Peter's College, Cambridge, and my twenty Baltimore coefficients of 1884. The term coefficients is abused by mathematicians. They use it for one of the two factors of the result. To me the professor and his class of students are coefficients, fellow-workers, each con-

tributing to whatever can possibly be done by their daily meetings together. I dislike the term lecture applied here. I prefer the French expression—"conference." I feel that every meeting of a professor with his students is rather a conference than a pumping in of doctrine from the professor, perhaps ill-understood and not well received by his students. The Scottish universities have enabled us to carry out this French idea of conference. In many of our classes the professor is accustomed to converse with his students sometimes in the form of *viva voce* examination and oftener, I hope, in the manner of the interchange of thoughts, the professor discovering whether or not the student is following his lecture, and being thus really helped in his treatment of the subject. I have had addresses also from my old Japanese students of Glasgow University, now professors in the University of Tōkiō, or occupying posts in the Civil Service and Engineering Service of Japan, for which I thank them heartily. I wish particularly also to thank my Baltimore coefficients for their address. They have been useful to myself in my own keen endeavour—unsuccessful, I must say—nevertheless keen—to know something about the true dynamics of light and ether and crystals. The addresses which I have received to-day contain liberal and friendly appreciation of all my published mathematical and physical papers, beginning in 1840, and ending—not yet I hope. The small proportion of that long series of writings which has led to some definite advancement of science is amply credited for its results. The larger part, for which so much cannot be said, is treated with unfailing and sympathetic kindness as a record of persevering endeavour to see below the surface of matter. It has been carried on in the faith that the time is to come when much that is now dark in physical science shall be seen bright and clear, if not by ourselves, by our successors in the work. I am much gratified by the generous manner in which these addresses have referred to the practical applications of science in my work for submarine telegraphy; my contributions to the advancement of theoretical and practical knowledge of the tides; my improvements in the oldest and next oldest of scientific aids to navigation, the sounding plummet and the mariner's compass; and my electric measuring instruments for scientific laboratories, for the observation of atmospheric electricity, and for electrical engineering. I now ask the distinguished men who have honoured me by presenting to me these addresses to accept for themselves personally, and for the societies represented by them, my warmest thanks for the great treasure which I have thus received—good will, kindness, friendship, sympathy, encouragement for more work—a treasure of which no words can adequately describe the value. I cordially thank the French Academy of Sciences for their great kindness in sending me by the hands of my loved and highly esteemed colleague Prof. Mascart the Arago Medal of the Institute of France. I thank all present in this great assembly for their kindness, which touches me deeply; and I thank the City and University of Glasgow for the crowning honour of my life which they have conferred on me by holding a commemoration of the Jubilee of my Professorship.

A more dignified and imposing ceremony than that which was now closed with the benediction pronounced by Prof. Stewart, was never witnessed at the University of Glasgow. Anything more striking and impressive of an academic nature it is hardly possible to conceive. The demeanour of the students and general public was respectful, and at the same time displayed the most enthusiastic regard for the hero of the occasion, and all the arrangements worked without the slightest hitch or fault.

In the evening at seven o'clock a grand banquet was given in the St. Andrews Halls to about six hundred gentlemen, including all the delegates and other distinguished strangers present at the celebration. On the platform of the hall three principal tables were arranged, at which were seated the Lord Provost, with Lord Kelvin and other gentlemen, who were afterwards to speak, or who, for various reasons, it was proper should be so honoured.

The Lord Provost occupied the chair at the first table, and was supported on the right by Lord Kelvin, His Excellency General Annibale Ferrero, the Italian Ambassador, the Right Hon. Lord Rayleigh, D.C.L., LL.D., F.R.S., Prof. Newcomb (Washington), Lord Overtoun, the Lord Justice General of Scotland, Prof. Picard (Paris), Lord Shand, General Sir Archibald Alison, Bart.; and on the left by the Earl of Rosse, K.P. (Chancellor of the University of Dublin), Sir Joseph Lister, Bart. (President of the Royal Society), Lord Napier and Ettrick, Prof. Quincke (Heidelberg), Dr. Gill (Astronomer-Royal, Cape of Good Hope), Signor Montefiore Levi (Brussels), Prof. Abbe (Washington), James A. Campbell, LL.D., M.P.

On the main floor of the hall were arranged fourteen tables, accommodating about forty guests each. The length of each table ran at right angles to the platform, so that each person could regard the after-dinner speakers comfortably without changing his position.

After dinner the front seats of the galleries round the hall were occupied by ladies, who had previously been received on entrance by Lady Bell and Mrs. Caird.

The Lord Provost began by saying—I have been entrusted with a message from Her Majesty the Queen, and, as is customary, I would ask you to stand while Her Majesty's message is being read. It is as follows:—

The Queen commands me to beg that you will kindly express to Lord Kelvin her Majesty's sincere congratulations on the occasion of the jubilee of his professorship in the Glasgow University. Her Majesty trusts that many years of health and prosperity may be in store for him and Lady Kelvin. The Queen is particularly gratified at the presence of so many eminent representatives from all countries of the world who have come to do honour to your distinguished guest.—(Signed) Arthur Bigge, on behalf of her Majesty.

This message was received with great applause by the company, and the knowledge that Her Majesty had joined her congratulations to those of the whole scientific world gave great and evident pleasure.

After the toasts of Her Majesty the Queen, the Prince and Princess of Wales, and the other members of the Royal Family had been duly honoured, the Lord Justice General of Scotland proposed that of the Houses of Parliament, coupling it with the names of Lord Rayleigh and Dr. James A. Campbell, member of Parliament for the Glasgow and Aberdeen Universities.

In concluding his reply on behalf of the House of Lords, Lord Rayleigh said:—

I suppose there are not very many here present who have followed more closely than I have done the writings with which our guest has furthered science for many years. It would be a commonplace to say that much which now passes as current science has its origin in those writings. But what gives to me more to think about, what is to me a matter of deeply-felt gratitude, is the twenty or twenty-five years' friendship with him that it has been my own privilege to enjoy—a friendship enlivened by many discussions, some perhaps not without a spice of controversy; but it would be difficult to convey the deep debt of gratitude due for all I have learned from him, in his writings or in his stimulating conversation. I feel, however, if I were to enlarge upon this subject, I should be very soon called to order, because I should be trenching on a toast which is soon to be proposed; but I feel I cannot abstain from saying a few words as a result of the very heartfelt feelings which I have on this subject.

The Lord Provost, in a most excellent and appreciative speech, next proposed the toast of the evening. He began by reading cable messages from the University of Toronto and the students of the University of Moscow. The latter ran as follows:—

To the celebrated Lord Kelvin, famous, learned, we send our congratulations, the Moscow University Students.

Telegrams of regret for absence were read from Lord Salisbury, Sir John Gorst, and others. The Lord Provost also read the following letter from the Principal of the University, unhappily laid aside by illness:—

The University, Glasgow, June 10, 1896.

My dear Sir James,—Will you allow me to express to you and to any others who may chance to notice my absence, my great disappointment and regret that I am not permitted to be

present next week at the banquet at which you are to preside, or at any of the other functions in connection with Lord Kelvin's jubilee. It would have been a great gratification to me to take part in the universal tribute of admiration and respect that is to be paid to the great man of science, and to give public expression to the esteem and affection which for many a long year I have felt for him as my colleague and friend. Acting under medical advice, however, I am reluctantly constrained, owing to a recent illness, from which I have not yet completely recovered, to refrain from taking part in the approaching ceremonials.—Very truly yours, (Signed) J. CAIRD.

The Lord Provost then proceeded, and, after a very interesting, but necessarily brief, sketch of Lord Kelvin's career, he concluded with the following graceful words:—

This life of unwearied industry, of universal honour, has left Lord Kelvin with a lovable nature that charms all with whom he comes in contact. Unaffected, ever wishful to get the opinions of others, courteous and kind, well might Prof. Huxley, after a memorable controversy, introduce Lord Kelvin as his successor in the presidency of the British Association with these words:—"Gentler knight never broke lance." Lord Kelvin, indeed, inspires love and reverence in all. His home life is love and melody. His helpmate is worthy of him, and greater cannot be said. Those who have the great privilege of their friendship, will in their hearts with fervent prayer add to the toast the wish that Lord and Lady Kelvin may long be spared to one another. I give you "Lord Kelvin, and hearty congratulations on the attainment of his jubilee."

The toast was pledged with great enthusiasm, and, on the call of the Lord Provost, cheers were raised for Lady Kelvin, the entire company rising and waving handkerchiefs. The cheering was again renewed when the organist played "See the Conquering Hero," followed by "For He's a Jolly Good Fellow," in which the company joined *con amore*.

On rising to respond, Lord Kelvin was greeted with enthusiastic applause. He said—

My Lord Provost, your Excellency, my Lords, and gentlemen,—First of all, I desire to express the deep and heartfelt gratitude with which I have heard the most kind and gracious message from Her Majesty the Queen, which has been read to us by the Lord Provost. But I cannot find words for thanks. I can only, on the part of Lady Kelvin and myself, tender an expression of our loving loyalty to the Queen. My Lord Provost, my Lords, and gentlemen, I thank you with my whole heart for your kindness to me this evening. You have come here to commemorate the jubilee of my University professorship, and I am deeply sensible of the warm sympathy with which you have received the kind expressions of the Lord Provost regarding myself in his review of my fifty years' service, and his most friendly appreciation of practical results which have come from my scientific work. I might perhaps rightly feel pride in knowing that the University and City of Glasgow have joined in conferring on me the great honour of holding this jubilee, and that so many friends and so many distinguished men, friends and comrades—day-labourers in science, have come from near and far to assist in its celebration, and that congratulations and good wishes have poured in on me by letter and telegram from all parts of the world. I do feel profoundly grateful. But when I think how infinitely little is all that I have done, I cannot feel pride; I only see the great kindness of my scientific comrades, and of all my friends, in crediting me for so much. One word characterises the most strenuous of the efforts for the advancement of science that I have made perseveringly during fifty-five years; that word is failure. I know no more of electric and magnetic force or of the relation between ether, electricity, and ponderable matter, or of chemical affinity, than I knew and tried to teach to my students of natural philosophy fifty years ago in my first session as Professor. Something of sadness must come of failure; but in the pursuit of science, inborn necessity to make the effort brings with it much of the *certaminis gaudia*—and saves the naturalist from being wholly miserable, perhaps even allows him to be fairly happy, in his daily work. And what splendid compensations for philosophical failures we have had in the admirable discoveries by observation and experiment on the properties of matter, and in the exquisitely beneficent applications of science to the use of mankind with which these fifty years have so abounded! You, my Lord Provost, have remarked that I have had the good fortune to remain for fifty years in one post. I cordially reply that for me they have been happy years. I cannot forget that the happiness of Glasgow University both for students and professors is largely due to the friendly and genial City of Glasgow in the midst of which it lives. To live among friends is the primary essential of happiness; and that, my memory tells me, we inhabitants of the University have enjoyed since I first came to live in it in 1832, sixty-four years ago! And when friendly neighbours confer material benefits, such as the citizens of Glasgow have conferred on their University in so largely helping to give it its present beautiful site and buildings, the debt of happiness due to them is notably increased. I do not forget the charms of the old college in the High Street and Vennel, not very far from the comforts of the Saltmarket, which was my home from 1832 till 1870. Indeed, I remember well when, in 1839, the old Natural Philosophy class-room and apparatus-room (no physical laboratory then) was almost an earthly paradise to my youthful mind. And the old College Green, with the ideal memories of Osbaldistone and Rashleigh and their duel, and Rob Roy intervening to prevent bloodshed, created for it by Sir Walter Scott, was attractive and refreshing to the end. But density of smoke and of crowded population in the adjoining lanes increased, and pleasantness, healthiness, and convenience of the old College both for students and professors diminished year by year. If, my Lord Provost, your predecessors of the Town Council, and the citizens of Glasgow, and wellwishers to the city and its university all over the world, and the Government, and the great railway company that has taken the old college for a passenger and goods station, had left us undisturbed on our ancient site, and had not given us our new college, I do not believe that attractions elsewhere would have taken me away from the old college—but I do say that the fifty years of professorship which I have enjoyed would have been less bright and happy, and I believe also less effective in respect to scientific work, than they have been with the great advantages with which the University of Glasgow has been endowed since its migration from the High Street. My Lord Provost, I ask you to communicate to your colleagues of the Town Council my warmest thanks for their great kindness to me in joining with the University to celebrate this jubilee. Your Excellency, my Lords, and gentlemen, I thank you all for the kind manner in which you have received the toast of my health proposed by the Lord Provost, and for your presence this evening to express your good wishes for myself.

Prof. W. T. Gairdner, F.R.S., in an interesting speech, proposed the representatives present from other Universities and learned bodies, coupling it with the names of His Excellency General Annibale Ferrero, Ambassador for Italy, Sir Joseph Lister, President of the Royal Society, and Prof. Simon Newcomb, Washington. These gentlemen replied as follows.

His Excellency General Annibale Ferrero, Ambassador for Italy, who, in acknowledging the compliment, spoke in French, said—My Lords, Ladies, and Gentlemen, when the honour was done me of asking me to speak in the name of so many illustrious men, I thought that it would be great hardihood on my part to accept a duty which would have better suited men whose name had already a place in the history of science. However, I thought that I had the honour of representing a country from which there have come great predecessors of Lord Kelvin, such as Galileo, Volta, and Galvani. In coming here to represent the scientific bodies of our respective countries we have merely the desire to render homage to the man of genius whose jubilee is being celebrated by the University of Glasgow, which has the honour of possessing him. But our presence is also intended to show that the whole scientific world desires to take part in recognising the services which Lord Kelvin has rendered to the human race. The light which shines to-day upon the University of Glasgow is like that of the sun. It does not belong to one country but extends to all nations. We owe special thanks to Prof. Gairdner for the way in which he has proposed the toast of the representatives of other institutions and learned bodies. We also owe a tribute of gratitude to the Corporation of Glasgow for the cordial and dignified welcome which has been accorded us. We have taken part in this jubilee celebration with the most lively feeling of admiration for the great man who is its object. The noble ceremony which we witnessed to-day in the University raised our spirits and touched our hearts. I cannot

better express our common thought than by saying that we have taken part in the apotheosis of science. I conclude by expressing the kindest wishes to the University of Glasgow, and our gratitude to Providence for having confided to us an incalculable treasure in the person of Lord Kelvin. May he be long spared to humanity.

Sir Joseph Lister said—My Lord Provost, my Lords and gentlemen, I have to thank Prof. Gairdner, my old friend, for the kind words in which he has referred to myself in the close of his speech, and this most distinguished company for the manner in which they have been received. It has been to myself a matter of unalloyed satisfaction to attend this grand celebration. A jubilee is sometimes attended with melancholy when it is felt that the man in whose honour it is held is failing in body and in mind, and that his life's work is over. No such cloud hangs over us to-day. It is true, as you are all aware, that some months ago Lord Kelvin experienced some indisposition. There was felt anxiety in some quarters, whether it might be prudent for him to undergo the fatigue and excitement necessarily attendant upon an occasion like this. Lord Kelvin came to London some weeks since, and he did me, as an old colleague, the honour of asking my advice. I looked into his case as carefully as I could, and it seemed to me that his ailment had been in its origin purely local, implying nothing of constitutional defect, and giving no reason to apprehend any ultimate impairment of bodily or mental vigour. A certain amount of care had been required at the outset, and this had been taken under the direction of the eminent men whose advice he had had in Glasgow; and I agreed with them in the opinion that the care might be gradually relaxed; and finally I took upon myself the somewhat serious responsibility of giving to Lord Kelvin *carte blanche* to behave as any ordinary mortal might do. Now, gentlemen, I venture to think that what we have seen and heard of Lord Kelvin in the course of the last two days justifies my boldness, and that we may confidently look forward to the fulfilment of the hope which he expressed this morning, that he may yet for many years to come pursue with unabated energy those magnificent researches which have already done so much to benefit humanity. There is another aspect of this occasion with regard to which I should like to say a word. It has been to me a matter of very great pleasure to witness the splendid vitality and vigour of the school in which I had once the honour of being a teacher. in palatial buildings, which may well excite the envy of us Londoners—a true teaching university in the full tide of prosperity and usefulness. I have also been exceedingly pleased to observe the friendly co-operation between the university and the municipality, of which this magnificent banquet is of itself sufficient evidence. The electrical illumination of the college buildings, which so largely promoted the success of last night's entertainment, was due to the liberality of the municipality, guided by the wise and bold policy of the Lord Provost. I visited to-day the Botanic Garden—that indispensable adjunct of an efficient university. In former days these gardens produced a painful impression upon those who visited them. They gave too clear an evidence that science was confined and cribbed for want of pecuniary means. Now all this is altered. The beautiful site has been extended and embellished, magnificent new houses have been erected, and everything bears the stamp on the one hand of scientific wisdom in their management, and on the other hand of ample resources. Now, all this is due to the beneficent rule of the municipality of Glasgow. I feel, therefore, that whether I look at this great celebration with regard to its essential object—the homage of the scientific world to our illustrious friend—or to the evidence which it has afforded of the prosperity of the University and the wise liberality of this great city, it has given me unmixed pleasure; and it has been a high privilege to have been permitted to take part in it.

Exhibition of diplomas and instruments, showing telegraph receiving and sending instruments, used for receiving and replying to congratulatory messages.

Prof. Simon Newcomb, Washington, U.S., replied for the Americans. He remarked—I feel that an apology is due to you in accepting the invitation to speak this evening, and thereby imperilling a certain reputation which I believe my country has for grace in after-dinner speeches. The fact is, that until it was too late I was really not aware America would have so many representatives here better able than I am to do justice to the occasion. But there is yet another reason why I was extremely unwilling to voice the sentiments which I know are entertained by all Americans on the present occasion. If among the friends of Lord Kelvin, who for twenty-five years have been in more or less intimate association with him, that one was to be selected of whom during that period he had most kindly spoken, and

awarded a praise that was perhaps the least deserved, I think it would have been the humble individual who now has the honour of addressing you. As Americans, you are aware how very close is our association with the great man of science whose jubilee we now celebrate. He first became known to us through his work in connection with the Atlantic cable of 1858, a cable which, those of you who now can remember it, ceased after a week or two of rather intermittent activity. It is quite true that on that occasion his fame was temporarily eclipsed by that of the operator who sent the messages from the end in Newfoundland. The name of this operator ran from city to city throughout the country. It had never been heard of before; it filled the land for those few brief days, and when the cable ceased to send the current, it disappeared almost for ever. For an explanation we had to refer to one of our most eminent men of science, who has lived, I think, wherever the English language is spoken—the author of the "Autocrat of the Breakfast Table"—and who published a theory or explanation of the whole phenomenon. This man was a living product of the galvanic action of the cable, and when the current ceased to pass, there was nothing left in the room he occupied but a cloud of organic elements such as man is made of. On the subsequent occasion of laying the cable in 1866, our guest again became well known to us for his work in promoting that object. Also, in our naval service, to which I have the honour to belong, we are in many ways most indebted to him. I do not think the name of any man is more familiar to the officers of our navy anywhere than that of Lord Kelvin, first, by his work on magnetism, and for the navigation of ships, and by his deep-sea sounding apparatus, as well as by many others of his inventions which relate to navigation. There are certain features of his work which, as one so long intimately associated with him, it may not be amiss that I recall. The first, and perhaps most unique, feature is the combination of abstract results with practical application. It has been the general—I do not know but that it has been the almost universal—rule that the men who have by their studies and thought promoted our knowledge of nature have not been those who have applied that knowledge to the direct benefit of mankind by inventing means for its application. I am not sure but that Lord Kelvin is the single, solitary exception to this rule. The ground covered by his work is certainly remarkable in its extent. The first knowledge I had of him—probably the first that those who cultivate mathematics know of him—is in connection with a journal published back in the forties, and known under different names at different times as the *Cambridge, London, and Dublin Mathematical Journal*. For a period, I believe, he was associated in the editorship of that journal. Now, it is worthy of remark in this connection, that at the present time sets of this journal can command a price that is almost fabulous in the public market from the mathematicians of the day. Then at this point he diverged from the doctrine which was said to have been laid down by one of the most eminent workers in the words, "I thank Heaven that I cultivate a science which cannot be prostituted to any useful purpose." In passing from the field of mathematics we come next to pure philosophy by saying that the theory of energy in its present form is, I think, very largely due to his work. This is, perhaps, the most far-reaching generalisation as to the laws of action that the world has seen; it enables us to see the beginning of the universe and to look forward towards its end. We all read discussions as to the age of the earth and the question whether the geologist has an indefinite bank of time on which he can draw cheques without limit. Yet another question of geology was that of the rigidity of the earth, in which I think his view is almost universally accepted. In this wide range of activity I think we may say that he has made few mistakes—perhaps we may say that he is almost unique in not having made any. I beg leave, on behalf of the foreign representatives, to thank you, my Lord Provost and the citizens of Glasgow for the very cordial reception we have met in coming here to present our congratulations to Lord Kelvin on this memorable occasion. We shall ever remember that reception, and I beg leave on behalf of all to again express the hope that our honoured guest of this evening may live for many years.

Prof. Story, at the suggestion of the Lord Provost, very gracefully proposed the health of Lady Kelvin, which was received with great applause. Lady Kelvin, who occupied a seat in the balcony, bowed her acknowledgments, and Lord Kelvin, replying for her, said—

Prof. Story has said well that I owe a great deal to Lady Kelvin, but he does not know how much I owe. No person in the world except myself knows how much of any results for science that it has been possible for me to arrive at are due to her co-operation. I thank you warmly for the very kind manner in which you, Prof. Story, have proposed this toast, and with which the company have received it.

After the toasts of the University and City of Glasgow, proposed by the Earl of Rosse, D.C.L., F.R.S., and the Lord Provost, proposed by Sir Henry Roscoe, F.R.S., had been duly honoured and replied to, the company joined in singing "God Save the Queen," and afterwards, on the request of Lord Kelvin, in singing "Auld Lang Syne."

Thus closed the celebration proper, a celebration almost unique in the experience of every one present for its grand simplicity, splendid enthusiasm, and entire success in every detail of arrangement. For the latter characteristic the Jubilee Committee deserve the highest credit, and its Secretaries, and others, among whom are the Rev. Professor Stewart, D.D., Clerk of Senate, Mr. Allen Baird, and members of the Senatus, who had charge of the University arrangements, may well be proud of the result of their labours.

Nothing in Lord Kelvin's reply to the toast of his health at the banquet was more characteristic of the man than his humble confession of failure to penetrate the mystery of the constitution of matter and of ether. It is no doubt true, as Lord Kelvin remarked, that the nature of electric and magnetic force, and the relation between ether, electricity, and ponderable matter, are still unknown to us; but Lord Kelvin's researches have been the means of enabling himself and others to unravel many of their phenomena, to connect these phenomena by general laws, and to marshal the forces of science for still further assaults on the unknown. The *certaminis gaudia* is not after all in this case mere joy of conflict, but the pleasure of obtaining by strenuous endeavour some view first of the very innermost secrets of nature, and what is of very great consequence and may in time include everything, an accurate conception of her method of working, and of the dynamical laws which govern her operations.

A number of delegates and others left Glasgow on Wednesday morning, but many remained and accepted the invitation of the Senatus to a special excursion on the Firth of Clyde. A special train was run from St. Enoch's station to Greenock, where the steamer *Glen Sannox* awaited the party. The morning was wet, but the ample saloon accommodation of the splendid steamer, with an awning erected on deck, provided sufficient shelter. The steamer headed down the Clyde instead of proceeding up Loch Long, where it was likely to be raining still more heavily, and proceeded past Largs, saluting Nether Hall, Lord Kelvin's country house at Largs, in passing, thence between the Cumbraes to the mouth of Loch Fyne, then round the Kyles of Bute, and back to Greenock in time to allow Glasgow to be reached before the departure of the limited mail train in the evening. Luncheon and tea were served on board. The weather cleared about midday, and the excursion proved most enjoyable to all, and there were many who ventured to go. Lord and Lady Kelvin with their party were present, and, it was gratifying to observe, seemed to be in excellent health and spirits in spite of the excitement and fatigues of the previous days.

A. Gray.

INTERNATIONAL CATALOGUE OF SCIENCE.

The approaching International Conference arranged by the Royal Society to consider proposals for an International Catalogue of Scientific Literature will be formally opened at the apartments of the Society in Burlington House on the morning of Tuesday, July 14. A reception of the delegates will be held by the

President of the Royal Society on the previous evening at Burlington House, and they will be entertained at dinner by the Society on the evening of the 14th at the Hôtel Métropole. On the 15th the delegates will be received by the Lord Mayor at the Mansion House, and on the afternoon of the 16th they will be entertained by Dr. Ludwig Mond, F.R.S., at a garden party at his house in Avenue Road. The total number of delegates appointed to attend the Conference amounts to forty, including representatives of the principal colonies of the Empire and the principal Governments of the world.

The following is a list of the delegates appointed to attend the Conference.

AUSTRIA.—Prof. Dr. Edmund Weiss; Prof. Dr. Ernst Mach.

BELGIUM.—Chevalier Descamps-David (President Institut International de Bibliographie); M. de Wulf (Member Institut International de Bibliographie); M. Paul Otlet (Member Institut International de Bibliographie).

BRAZIL.—Dr. João Ribeiro (Professor "Gymnasio Nacional").

DENMARK.—Prof. Christiansen (Universitet, Copenhagen).

FRANCE.—Prof. A. Milne-Edwards (Membre de l'Institut, &c.); Prof. G. Darboux (Membre de l'Institut, &c.); Prof. Troost (Membre de l'Institut, &c.); Dr. J. Deniker (Librarian, Muséum d'Histoire Naturelle, Paris).

GERMANY.—(Names not yet received).

GREECE.—M. Avierinos M. Averoff (Greek Consul at Edinburgh).

HUNGARY.—Prof. August Heller (Librarian, Ungarische Akademie, Buda-Pesth); Dr. Theodore Duka (London).

ITALY.—General Annibale Ferrero (Italian Ambassador in London).

JAPAN.—Hantaro Nagaoka (Assistant Professor, Science College, Tōkiō); Gakutaro Ozawa (Assistant Professor, Medical College, Tōkiō).

MEXICO.—Señor Don Francisco del Paso y Ironcoso.

NETHERLANDS.—Prof. D. J. Korteweg (Universiteit, Amsterdam).

NORWAY.—(Names not yet received).

PORTUGAL.—The Portuguese Minister in London (Señhor D'Antas).

RUSSIA.—Privy Councillor Stasow (First Librarian, Imper. Publičnaja Biblioteka, St. Petersburg).

SWEDEN.—Dr. E. W. Dahlgren (Librarian, Kongl. Svenska Vetenskaps Akademie, Stockholm).

SWITZERLAND.—The Swiss Minister in London (M. Bourcart); Prof. Dr. F. A. Forel (Président du Comité Central de la Société Helvétique des Sciences Naturelles).

UNITED KINGDOM.—Representing the Government: Right Hon. Sir John E. Gorst, M.P. (Vice-President of the Committee of Council on Education). Representing the Royal Society of London: Prof. Michael Foster, Sec. R.S., Prof. H. E. Armstrong, F.R.S., Mr. J. Norman Lockyer, C.B., F.R.S., Dr. Ludwig Mond, F.R.S., Prof. A. W. Rücker, F.R.S.

UNITED STATES.—Dr. John S. Billings (U.S. Army); Prof. Simon Newcomb, For. Mem. R.S. (U.S. Nautical Almanac Office).

CANADA.—The High Commissioner for Canada (the Hon. Sir Donald A. Smith, G.C.M.G.).

CAPE COLONY.—Mr. Roland Trimen, F.R.S.

INDIA.—General Sir Richard Strachey, F.R.S.

NATAL.—The Agent-General for Natal (Walter Peace, C.M.G.).

NEW SOUTH WALES.—(Appointment awaiting confirmation).

NEW ZEALAND.—The Agent-General for New Zealand (the Hon. W. P. Reeves).

QUEENSLAND.—The Agent-General for Queensland.

NOTES.

WE are asked to state that a zoologist with experience of deep-sea dredging is required for the Belgian Antarctic expedition. Intending applicants should communicate with Lieut. de Gerlache, Commander of the expedition, at Sandefiord, Norway.

PROF. DR. G. NEUMAYER, the Director of the Deutsche Seewarte, reached his seventieth birthday on Sunday last. We join with German scientific papers in congratulating Prof. Neumayer upon his numerous contributions to natural knowledge, and in the hope that science may have the benefit of his assistance for many years to come.

DR. D. GILL, F.R.S., has been elected a Correspondant of the Paris Academy of Sciences.

WE regret to announce that Sir Joseph Prestwich died on Tuesday morning, after a short illness. By his death science has lost a devoted student, whose numerous papers in the various departments of theoretical, observational, and practical geology testify to a career of earnest and careful work. He was born in in 1812, and became a Fellow of the Royal Society in 1853.

MR. J. H. MAIDEN has been appointed Government Botanist and Director of the Botanic Gardens at Sydney, in succession to Mr. Charles Moore, who has recently retired after a service, in these capacities, of nearly half a century.

MAJOR ARTHUR GRIFFITHS, one of her Majesty's Inspectors of Prisons, has been appointed by the Home Secretary to represent her Majesty's Government at the International Congress of Criminal Anthropology to be held at Geneva in August next.

WITH reference to the tornado at St. Louis on May 27, we learn from *Science* that, with commendable promptness, the Washington Weather Bureau issued, on May 29, a special storm-bulletin showing the weather conditions over the United States on May 26–28. The Chicago 8h. a.m. forecast on May 27 predicted severe thunderstorms for Illinois and adjoining States during the latter part of the day, and a special warning was issued from Washington at 10h. 10m. on that morning.

THE Northern Province of Japan has recently been visited by a series of destructive earthquakes. Within twenty hours, on the 15th and 16th insts., no less than 150 shocks were felt. Nearly the whole of the town of Kamaishi has been destroyed, with the reported loss of one thousand lives. Three of the shocks appear to have been of exceptional severity, for, according to information we have received from Prof. Vicentini, they were registered by his microseismograph at Padua. The first pulsations began there at 10h. 45m. a.m. (Greenwich mean time) on the 15th, and lasted till 0h. 10m. p.m.; the second continued from 7h. 28m. to 8h. 30m. p.m.; the third and strongest began at 11h. 14m. p.m., and ended at 0h. 2m. a.m. on the 16th inst. The great sea-wave, which accompanied the earthquake, extended over seventy miles of the north-east coast of Japan, destroying many towns, and drowning, it is feared, about ten housand persons.

A DEVOTED student of natural history, whose name is known to most zoologists, and whose observations have greatly enriched ornithology, has just passed away in the person of Lord Lilford. Numerous notes by him on British birds, and on the ornithology of Spain and of the shores of the Mediterranean, have appeared in the *Zoologist* and the *Ibis*, the journal of the British Ornithologists' Union, of which he was President. Last year he published an excellent volume on the birds of his native county, Northamptonshire, with beautiful illustrations, and the thirty-second part of his "Coloured Figures of the Birds of the British Islands," which was issued only in April last, almost

completes that work. Lord Lilford will be remembered and regretted by naturalists all over the world.

M. TONY NOËL has (says the *British Medical Journal*) just finished a statue of Pasteur, to be placed in the market-place of Alais, where the illustrious investigator made his researches in the diseases of silkworms. The statue is declared by the relatives and friends of M. Pasteur to be an excellent likeness, and artistically it is a very successful piece of work. Pasteur is represented erect, gazing fixedly at a sprig of mulberry covered with cocoons which he holds in his left hand. At his feet is a young girl in a graceful attitude handing him other cocoons. Near at hand are a microscope and a box of scientific instruments. M. Berthelot, who in company with M. Roux carefully inspected the statue, is said to have exclaimed: "Je revois Pasteur tel qu'il était il-y-a vingt-cinq ans."

WE regret to announce the death, on the 14th inst., of Dr. H. B. Pollard, lecturer on biology and comparative anatomy at Charing Cross Hospital. Elected a scholar of Christ Church, Oxford, in 1885, Dr. Pollard graduated B.M. with first class honours in morphology in 1890, and concurrently gained similar distinction in the London intermediate and final B.Sc. examinations. He subsequently studied for two years under Prof. Wiedersheim at Freiburg, and in 1892 was appointed to the Oxford table at Dr. Dohrn's laboratory at Naples. In 1893 he was elected Berkeley Fellow of the Owens College, Manchester, and in 1895 lecturer at Charing Cross Hospital. He was granted the degree of D.Sc. by London University for a thesis on Polypterus. Dr. Pollard made a special study of fish, and in a series of papers contributed to German scientific periodicals, he originated a theory of their development which has received considerable attention from biologists. He was writing a text-book on the subject at the time of his death, which took place at Dover, in his twenty-eighth year. He was apparently stunned by a fall while bathing and drowned.

FOR the opening of museums and art galleries on Sundays we are undoubtedly very largely indebted to the zeal of Mr. Mark Judge, the Honorary Secretary of the Sunday Society. For some years the Society cried aloud in the wilderness, but few of the multitude paid heed, though such men as Darwin, Huxley, Romanes, Spottiswoode and Tyndall, only to mention a few of the supporters who are gone, became apostles of the movement. From the time when the Society was founded, thirty years ago, Mr. Judge has advanced its objects with the pertinacity which comes from conviction, and has thus educated public opinion on the subject of Sunday reform. The objects have now been attained, and there is a feeling that the services rendered by Mr. Judge in support of them should be publicly recognised. A Committee has therefore been formed to appeal, for subscriptions for a testimonial to Mr. Judge. It is hoped that a ready response will be made to the appeal, as a token of gratitude for the boon of Sunday opening. The Chairman of the Testimonial Committee is the Rev. S. A. Barnett, and the Hon. Sec. and Treasurer, Prof. Corfield, to whom subscriptions may be sent at 19 Savile Row, W.

WE learn from *Science* that the party from Cornell University which will embark with Lieut. Peary on the *Kite* is as follows. R. S. Tarr, professor of dynamic geology and physical geography; A. C. Gill, professor of mineralogy and petrography; J. A. Bonstell, assistant in geology; T. L. Watson, fellow in geology; E. M. Kindle, scholar in palæontology; and J. O. Martin, special student in entomology. It is the purpose of the party to make as thorough a geological study as is possible in five or six weeks, of the region near the Devil's Thumb, at the south end of Melville Bay, and in addition to this to make collections of flora and fauna. Another party will also sail with Lieutenant Peary, under the leadership of A. E. Burton, professor of civil engineering in the Massachusetts Institute of Technology. This party will land at the great Umanak Fiord; they will make pendulum observations, natural history collections, and study the glacial phenomena. Lieut. Peary himself will proceed north as far as Cape Sabine at the entrance of Smith Sound. He will also endeavour to explore Jones Sound. He will be accompanied by Mr. Albert Operti, the artist, who will take casts of the Cape York natives for the purpose of making models for the American Museum of Natural History, New York.

IN connection with the note in NATURE of June 18 (p. 158), with reference to the instruction in meteorology in the University of Odessa, our attention has been drawn to a circular relating to meteorological observations in schools, recently prepared for the Connecticut State Board of Education by Mr. R. De C. Ward, Instructor in Meteorology in Harvard University, and published by the Connecticut Board. The *Document* (No. 10, 1896) points out that the time has come when meteorology should be systematically taught in schools, and it indicates the lines along which the elementary study of the subject should proceed in order to be most thorough and useful. In addition to the registration of observations without the use of instruments, including current weather and the state of the sky, it is not proposed to attempt anything more than records of temperature, direction and force of wind, and rainfall during the early years of the grammar-school course. Such elementary work cannot fail to attract both teachers and scholars, and to lay a foundation on which, in after years, a more advanced study of meteorology (including the practical use of daily weather maps) may be built up.

THE Hawke's Bay Philosophical Institute, New Zealand, is fortunate in having such a generous and broad-minded friend as the Rev. William Colenso, F.R.S., as their President. At the opening of the Institute's session in May, after delivering an animated address, Mr. Colenso put before the meeting a scheme for the foundation of a museum to take the place of the present museum at Napier. He offered to give towards the realisation of his scheme the sum of £1000 and a freehold site, and to supplement this with a second donation of £500 so soon as £500 was given by some one else. The total amount required to establish the museum is about £4000. Referring to the conditions of gift, Mr. Colenso said: "The museum must be a building which will be open every day of the week and Sunday afternoons too. I find that this is the case in Auckland, where large numbers visit the museum on Sunday afternoons. And what better use can a man give to his time than in the observance of the wonderful works of his Maker? There is another proviso, and that is that the building must only be used for the purposes of a museum and library. There must be no concerts, no Liedertafels, no spouting, no mutual admiration societies, no globe-trotters, no tourists, and no parsons. I will not give a penny for persons of that kind. I have received a letter asking for assistance for a museum in my native town in England. There the money has to be raised by a certain time. So in Napier it must be raised by December 31. The deed would be vested in five trustees, who should be generous and businesslike men, with a keen interest in the project. The museum proposed would be a museum for the East Coast, not only for Hawke's Bay proper, or for the old provincial district, but for Poverty Bay and Gisborne and the country stretching up to the East Cape." There should be no difficulty in raising the money required for the consummation of the scheme which Mr. Colenso has in mind, and towards which he is willing to contribute so liberally.

Dr. Bruni, of Naples, has recently contributed an important paper to the *Annales de l'Institut Pasteur*, corroborating earlier investigations on the association of the typhoid bacillus with cases of osteomyelitis. The bacteriological study of this disease has recently been actively pursued, and a French physician not long ago published statistics of ninety cases in which he found the *Staphylococcus aureus* seventy times, and the typhoid bacillus four times. Particular interest attaches to the connection of Eberth's bacillus with osteomyelitis, since Orloff, Fränkel, and others have shown that this organism is frequently found in osseous tissue, whilst of especial importance is the discovery made by Chantemesse and Widal, that it has a particular predilection for the marrow of bones. Osteomyelitis may declare itself not only during the course of typhoid fever, or during the period of convalescence, but also a long time after the recovery has been completed. That a connection was possible between typhoid fever and subsequent manifestations of osteomyelitis was first indicated by Keen in 1878; but for the more precise information which is now at our disposal on this subject, we are indebted to Chantemesse and Widal. Dr. Bruni describes a most interesting case of osteomyelitis in which the typhoid bacillus was found in the marrow of the left tibia, six years after the patient had recovered from an acute attack of typhoid fever. Most careful tests were made, including Pfeiffer's ingenious serum reaction, to correctly diagnose the bacillus found as that of typhoid, and there appears to be no doubt that Dr. Bruni has furnished fresh evidence of the new *rôle* which may be assumed by this much-dreaded microbe.

During last year M. Flammarion made some interesting experiments as to the effect of lights of different colours upon vegetable growth (*Bull. Soc. Ast. France*, June). On July 4, eight identical sensitive plants, which had been sown at the same time, were selected for experiment. These were placed two by two in similarly constructed glass boxes, of which the sides were of different colours, one being red, one green, one blue, and another of ordinary clear class. All were exposed to precisely the same meteorological conditions throughout. The rates of growth were as follows:

	Red. m.	Green. m.	Blue. m.	White. m.
Sept. 6	0·220	0·090	0·027	0·045
,, 27	0.345	0·150	0·027	0 080
Oct. 22	0·420	0·152	0·027	0·100

Thus, while the plants exposed to blue light made no progress whatever, those exposed to red increased their height fifteen times. The latter, moreover, acquired an extraordinary degree of sensitiveness. Similar results, but not so strongly marked, were obtained with geraniums and other plants. The fact that the plants exposed to white light grew less rapidly than those which were under red glass, although receiving the same amount of red radiations, seems to suggest that the presence of blue light in the former case not only did not accelerate the growth of the plants, but actually retarded it.

In vol. viii. of the *Proc. Roy. Soc. Victoria* (Melbourne), recently published, Mr. R. Etheridge, jun., describes some Trilobite remains from Heathcote, on the western side of Mount Ida, which are of extreme interest as an addition to the scanty Cambrian fauna of the Antipodes. Although occurring only as casts, the characters of the head and pygidium appear to be clearly shown, so much so that Mr. C. D. Walcott, from an examination of careful drawings, unhesitatingly referred them to the Middle Cambrian. As the result of a critical comparison, Mr. Etheridge is unable to identify them with any known genus, and has named the specimens *Dinesus ida*. Along with this trilobite occurs a brachiopod, which seems very similar to *Lakhmina*, a form described from the Cambrian of the Salt Range, India. It is to be hoped that this scanty fauna, which is the only unquestionable *Middle* Cambrian fauna yet found in Australia, and which seems to have no close relation to any of the other Cambrian faunas of that country, may soon be added to, for it is certain that the trilobites are a most promising group for the determination of the geographical life-provinces which may have existed in these remote times. In the same volume there is a revision of (with additions to) the fauna of the Table Cape Beds, Tasmania, by Mr. Pritchard, who regards it as Eocene.

The *Agricultural Gazette* of Cape Colony publishes a letter sent by Sir Ferdinand von Mueller to Sir Hercules Robinson, the Governor of the Colony, and appealing for a reserve-ground for the preservation of rare Cape plants. As the veteran botanist of Victoria points out, the vegetation of South Africa is the richest in the world, not only as to number of species, but also as containing an astounding variety of plants of special and peculiar type, aggregated chiefly in the south-western provinces and occurring nowhere else. Hundreds of these are quite local and restricted to very circumscribed areas. They are sure to be swept out of existence altogether, unless special provision is made for their preservation; and it is on that account that the appeal is made for a wild-garden or reserve for the conservation of Cape plants in areas where they can be maintained for the knowledge of generations to come. It may be said that botanic gardens exist already in several parts of the colony; but in a report upon Baron von Mueller's proposal, Prof. Mac Owan remarks: "These places can only exist by making themselves into a lounge or pleasaunce of idle hours for the population living close by. I speak as one who knows, for it was my lot to run one of these for fourteen of the hardest and most unsatisfactory years of my working life. The conditions of support compelled the place to grovel down into a nursery-garden on commercial lines, in order to get money enough to keep it presentable for the daily stroller. Nor did I ever dare to plant up any single portion of it with typical representatives of our Flora. The public would have taken the alarm at once. They care nothing for the special prehistoric flora of the land they live in, compared with the newest hideous abortion in chrysanthemums. . . . So that some of the gardens which we complaisantly call botanic, have it in them to stand between the living and the dead, and stop the slow and sure extinction of the most ancient and interesting part of our Cape Flora. This state of things, brought home to me yearly as I traverse the same solitudes each season, and note the increasing scarcity of rare plants, has been much in mind; but I do not see any other way of dealing with the matter, than by the reserve, now recommended, of chosen localities for all time and inalienable." But much as this is to be desired, Prof. Mac Owan has to confess that the idea is not likely of even approximate fulfilment.

Under the editorship of Dr. Götz Martius, Professor of Philosophy in the University of Bonn, the first part of a new journal has appeared, entitled *Beiträge zur Psychologie und Philosophie*. The present number is devoted to considerations bearing on colour-vision, and contains three papers by Dr. Martius on the brightness of negative after-images, on a new method of determining the brightness of colours, and on the conception of specific brightness of colour-sensation. In addition to these, Herr Friedrich Kretzmann contributes a note on the brightness of complementary mixtures.

In *L'Elettricista*, Prof. A. Róiti describes a new tube for the production of Röntgen rays, in which the bottom end is covered with a cap of aluminium instead of glass, thus allowing freer passage of these rays. According to the figure given, it appears that this cap is used as the anode, the kathode being a concave speculum of aluminium facing it. By polishing with emery

the end of the tube over which the cap fits, the whole is made perfectly air-tight so that good vacua can be obtained. For taking photographs of bones, &c., none of the other tubes that the author had constructed or purchased approached anywhere near the present one in respect of intensity and sharpness of definition.

In the *Journal of Physiology*, Dr. Lazarus Barlow has pointed out that before the laws of osmosis, deduced from the final osmotic pressure, freezing point, &c., can be applied to the explanation of biological problems, it is necessary to determine whether the initial rates of osmosis of substances bear constant ratios to their final osmotic pressures, and whether the presence of proteid substances in the solutions affects the initial rate of osmosis. The author has found that the initial rates of osmosis cannot be determined from observations of the freezing points of solutions, and that proteid substances, even when present only in minute quantities, markedly diminish the rate of osmosis. In a subsequent paper, Dr. Barlow applies these conclusions to the consideration of lymph-formation, and describes observations of the specific gravity of the blood, of voluntary muscle, and of lymph, which have an important bearing on the question. In his conclusion the author summarises the evidence in favour of the occurrence of osmosis and increased filtration as the effective factors in causing the increased outflow of lymph that is seen after the injection of a crystalloid into the blood, as well as the evidence against the view that osmosis and increased filtration alone account for the observed phenomena.

A valuable little pamphlet on "Coal Mining," full of information on many questions of practical importance in the working and use of coal, has been received from Mr. W. Galloway. The pamphlet is an excerpt from the "Handbook of the Cardiff Exhibition," and may be obtained from the office of the *Western Mail*, Cardiff.

During the spring and summer, Herr P. Sintenis has been carrying out a botanical exploration of the mountains of the Peloponnesus. After visiting Volo in Thessaly, he proposes to investigate the almost unknown flora of the south-western portion of the Pindu Chain.

At the time of his death Mr. Seebohm had almost completed an exhaustive monograph on the "Family of Thrushes" We learn that Dr. Bowdler Sharpe has undertaken to finish the work, and that it will shortly be published by Messrs. Henry Sotheran and Co. It will be illustrated with nearly 150 coloured plates, and the edition will be limited to 250 copies.

A short account of the proceedings of the Sixth International Geographical Congress, held in London last July, appeared in these columns at the close of the Congress. The official Report, containing the addresses delivered and papers read before the Congress, together with a brief historical statement, has now been published. When it is remembered that the papers are in several languages, and that authors are often procrastinators in the matter of reading and returning proofs, the appearance of the Report within a year of the Congress is commendable. Most of the papers are of international interest, and all of them are of geographical value. The two Secretaries of the Congress, and Dr. Mill, who has done the editorial work in connection with the Report, are to be congratulated upon having brought their difficult tasks to a satisfactory conclusion.

The second edition of the valuable "Statistical Atlas of India" has been published by the Government of India, and is obtainable from Mr. Edward Stanford. The Atlas originally appeared in 1886, but since then another census of India has been taken, and new information has been obtained, so that a revision of the maps was necessary. The maps and diagrams in the Atlas give a good general idea of the character, inhabitants, and resources of India, and illustrate the commercial, financial, and educational condition of the country. Explanatory chapters are contributed by persons having special knowledge of the subjects of them; thus, Sir E. C. Buck writes on physical configuration, irrigation, famine, revenue and rent systems; Dr. W. King, on the geology of India; and Mr. J. Eliot, on the rainfall and climate. Mr. George Watt deals with crops and economic minerals; Mr. B. Ribbentrop with forests; Mr. J. E. O'Conor with prices, foreign trade, finance and taxation; and Veterinary-Lieutenant H. T. Pease with horses and live-stock. The Atlas is an excellent piece of work, which conveys by concise text and clear illustration, an abundance of information concerning our great Indian Empire.

The additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*, ♂) from South Africa, presented by Mr. Vernon E. Barratt; a Black-eared Marmoset (*Hapale penicillata*) from South-east Brazil, presented by Mr. S. Osborn; two Golden Eagles (*Aquila chrysaetus*), two Peregrine Falcons (*Falco peregrinus*) from the Isle of Mull, presented by the Maclaine of Lochbuie; two Wood Owls (*Syrnium aluco*), a Short-eared Owl (*Asio brachyotus*), British, presented by Mr. A. Farquahar Wilson; a Ring-necked Parrakeet (*Palæornis torquatus*) from India, presented by Miss Smith; a Black-headed Conure (*Conurus nanday*) from Paraguay, presented by Mrs. Baird; two Peafowls (*Pavo cristatus, albino*) from the Transvaal, presented by Mr. F. A. Noyce; a Mona Monkey (*Cercopithecus mona*), two West-African Love-Birds (*Agapornis pullaria*) from West Africa, a Crab-eating Raccoon (*Procyon cancrivorus*) from South America, deposited; an Australian Fruit Bat (*Pteropus poliocephalus*) from Australia, purchased; a Burrhel Wild Sheep (*Ovis burrhel*), a Thar (*Capra jemlaica*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Return of Comet Brooks (1889 V.).—A telegram from Kiel announces that Brooks's periodic comet was observed by Javelle at Nice on June 20. At 14h. 17·4m. mean time it was in R.A. 22h. 25m. 30s., Decl. 18° 33′ 59″ S. The comet is now in the southern part of Aquarius, and rises about midnight. It is interesting to note that the observed place of the comet shows a very close agreement with Dr. Bauschinger's search ephemeris printed in Nature (vol. liv. p. 84).

Visibility of Solar Prominences.—Prof. Hale has brought together some facts which emphasise the importance of the work which may be done by observers of solar prominences at the time of a total solar eclipse without going to view the eclipse itself (*Astrophys. Jour.*, May). It is pointed out that in 1870 Tacchini concluded that the dimensions of prominences spectroscopically observed in full sunshine, and measured in Hα light, were considerably smaller than those measured telescopically during an eclipse. In 1883 the same observer discovered the "white prominences," and found that these were not visible in the spectroscope immediately after the eclipse. Similar results were obtained in 1886, and it was further ascertained that the spectrum of a white prominence consisted principally of the H and K lines, the hydrogen lines being extremely feeble.

The results obtained during the eclipse of 1893 furnish valuable data as to the relative efficiency of the different methods of registering the forms of the prominences, as the spectroheliograph at Chicago was employed on that occasion, and a complete set of eye observations was secured by Fenyi at Kalocsa. A comparison is drawn between these non-eclipse observations and the forms of the prominences as photographed nearly at the same time by Prof. Schaeberle, in Chili, and by Mr. Fowler with the prismatic camera in Af ca. It turns out that one of

the largest prominences depicted in all the photographs was not seen at all at Kalocsa. The results with the spectroheliograph were not of the best, owing to haze; but from all available facts, it seems to be established that the white prominences are spectroscopically invisible because they shine chiefly by H and K light. Nevertheless, light of the same refrangibility in the electric arc undoubtedly appears violet; but it may be, as Prof. Hale suggests, that the violet tinge is overlooked in the presence of the more conspicuous colours during an eclipse. The best results obtainable with the spectroheliograph, when K light is utilised, compare very favourably in sharpness of definition, as well as in the rendering of faint details, with the best photographs taken during an eclipse.

SHOOTING-STAR RADIANTS.—In connection with a table of radiant points observed at Hong Kong, Dr. Doberck refers to several interesting points relating to the phenomena of shooting-stars (*Ast. Nach.*, 3360). It is pointed out that the long continuance of some of the radiants is accounted for by parabolic motion, while others can possibly be explained by hyperbolic motion. In explanation of some of the radiants having somewhat similar elements, it is suggested that they were possibly associated with different tails of the same comet.

Owing to the fact that the meteorites are heated to incandescence nearer the earth in the evening than in the morning, there is a small decrease in the average magnitude of shooting-stars during the night; before 9 p.m. the average brightness is mag. 2·7, while of those seen later it is 3·2. Again, on account of the earth's movement, the duration decreases from 0·9 sec. between 6 and 8 p.m. to 0·5 sec. between 8 and 11 p.m., and to 0·3 sec. between 11 p.m. and 4 a.m. Up to 11 p.m. the mean length of path is 15°, and afterwards 13°. The average duration, length, angular velocity per second, and the numbers of shooting-stars observed, classified according to magnitude, are shown in the following table:—

Mag.	Duration. s.	Length. °	Velocity. °	Number.
1	0·9	19	21	60
2	0·4	14	35	79
3	0·3	13	43	130
4	0·3	12	40	128
5	0·2	12	60	97

The majority of the shooting-stars below third magnitude were probably hidden by haze and artificial light.

KEPLER AND HIS WORK.—In a little pamphlet entitled "Kepler's Lehre von der Gravitation" (Halle, Max Niemeyer), Dr. Ernst Goldbeck gives an interesting and appreciative account of Kepler and his work. The point principally elaborated is a main difference between Kepler's methods and those pursued by Ptolemy and the older astronomers. These latter were content to solve the problem of celestial mechanics on purely mathematical lines. They were instructed in the shape of the orbits and their dependence on time; they could foretell the place of an object at a definite epoch, and this satisfied their astronomical needs. Kepler, however, the forerunner of the modern school, is concerned in the character and the operation of the force, on which these motions depend. The points surveyed by the author as affecting the development of Kepler's views in his approach to a gravitational theory of the earth are: (1) The transference of the centre of the solar system from the earth to the sun, and the consequent disturbance of Aristotle's views. (2) The impetus given to mechanical inquiry by Gilbert's magnetical investigations. (3) The discovery of the coincidence of tidal phenomena with the position of the moon, and consequently the suggested attraction. (4) The telescopic examination of the moon by Galileo, and the confirmation of the suspected identity of its general character with that of the earth. Kepler's work on Mars, and his endeavours to trace the nature of the connection between the sun and the planets, are graphically described, and the whole pamphlet well repays careful study.

SCIENCE AND SOCIETY AT THE CENTRAL TECHNICAL COLLEGE.

THE object of the conversazione at the Central Technical College, Exhibition Road, on Friday, June 12, was to enable the scientific public to witness the ordinary working life of the students there. Consequently, while in deference to the lady visitors, the staircases and corridors were rendered attractive with arches of palms, arm-chairs, arc lights, and Hungarian airs, neither the blossoms, the banners, nor the band, were allowed to intrude on the apparatus and machinery, which were left as in every-day use.

Laboratory sinks remained sinks, and were not converted into make-believe flower-boxes; while no green baize covers hid the traces of oil and tools on the workshop benches, nor made them resemble extemporised billiard tables.

The Lord Chancellor, as Chairman of Council, and Lady Halsbury, received the visitors, and conspicuous amongst the 1700 were the Masters of many of the City Companies wearing their chains of office.

Exactly twelve years ago to-day (June 25, 1896) the Central Technical College was opened by the Prince of Wales, who expressed the opinion, "that the opportunities for advanced instruction, which will be afforded in the well-arranged laboratories and workshops, will enable the managers and superintendents of our manufacturing works to obtain more readily than hitherto the higher technical instruction which is so essential to the development of our trade and commerce." And, on the same occasion, the late Lord Selborne—the then Lord Chancellor—stated that "in the several laboratories with which this College is provided, new and increased facilities will be afforded for the prosecution of original research, having for its object the more thorough training of the students, and the elucidation of the theory of industrial processes."

An examination of the laboratories and workshops by the visitors at the conversazione, made it clear that the aims initially laid down for the working of the Central Technical College have been steadily kept in view. The Department of Mechanics and Mathematics showed the apparatus which had been developed for familiarising students with the laws of motion and force. Electric clocks transmit time-signals to quick-running Morse instruments for chronographically marking the instants of various experimental events. To measure "g" the falling body is started electrically, its moment of arrival noted electrically, and the interval measured with a vibrating tuning-fork; while for slower motions, such as that of a body rolling down an inclined plane, the electric current that liberates the ball starts a stream of water flowing from a water-clock, which again is instantly stopped on the ball touching an electric trigger placed at any desired point of its path. Apparatus for measuring centrifugal forces, studying impact, finding moments of inertia, timing the vibrations of pendulums, measuring the extensions of wire, &c., make us wish that, when, as boys thirty or forty years ago, we laboured through "little Newth," acquired a particle of Tait and Steele, and struggled with the rigidity of Routh's Dynamics, some Maxwellian demon had opened the door of Prof. Henrici's laboratory, and shown us so vivid a realisation of the principles of what, in the misleading jargon of that day, was called "statics and dynamics," with its "accelerating forces" and "moving forces."

In the same department were seen calculating machines and quadric surfaces, planimeters and plaster of Paris models, integraphs for solving differential equations, and integrators for evaluating areas; while the smooth working of the latest form of Prof. Henrici's harmonic analyser, by means of which ten coefficients in a Fourier's series can be determined by going only once over a curve, led the engineer to speculate on the time when all calculations, however complex, would be done by turning a handle, and when the brain would be left quite free to think and originate.

So much attention has of late been given by School Boards and County Councils to the establishment of manual training classes, that the collection of exercises in wood-working in the Carpenter's Shop of the Engineering Department, could not fail to attract attention. But more attractive still was the laboratory for testing materials, where the deliberate motion of the lever of the 100-ton machine, stretching steel plates until they broke, and automatically writing the history of the experiment with Prof. Unwin's stress-strain-recorder, was as fascinating to the lady-visitors as to the engineers who accompanied them. And how complete is the investigation that the students can make on the properties of the materials used by the engineer and builder, could be gathered from seeing the smaller machines which were bending thick beams of wood, stretching wires, and breaking blocks of cement, as well as from examining those specially designed for testing lubricants, gauges, and the elastic constants of materials, such as the screw and mirror extensometers and compressometers designed by Prof. Unwin.

The desire of every lad to make something is gratified and educationally directed in the Engineering Workshop, which is liberally fitted with milling, planing, shaping, and slotting machines, and four of the lathes, we were told, had been made by the students themselves, while one weighing three tons, and having a 10-foot gap bed, we saw in process of construction.

The economy of a De Lavel steam turbine, running at 32,000 revolutions a minute, and of a Tower spherical engine, were being tested in the Steam Laboratory, while a 40-horse power condensing engine, specially designed to illustrate the effect of varying the conditions of working, has fitted to it a very satisfactory hand-brake, indicator gear, and arrangements for measuring the circulating water, the condensed steam, the jacket and receiver drainage, &c. And, as a memento of the improvements that can be effected in prime movers by experimental inquiry, there stands the very engine used by the late Mr. Willans in his classical investigations on steam engine economy, cut through so as to expose a sectional view of the cylinders, pistons, and valves.

Adjoining the Steam Laboratory is the boiler-room, where in addition to the Lancashire and Cornish boilers, used for generating steam for the engines, is a Babcock and Wilcox boiler, used exclusively for boiler and fuel tests, with its accompaniments of feed-water measuring tanks, coal-weighing apparatus, dasymeter for determining the percentage of carbonic acid in the furnace gases, &c.

In the laboratories of the Physical Department are many instruments and pieces of apparatus that have been developed there, and specimens of which are now to be found in other colleges, electrical works, and electric lighting stations. In the dynamo room are speed cones by means of which the speed of any dynamo can be varied between wide limits, and, what is equally important for experimental purposes, can be kept at a constant value independently of variations in the speed of the engine, or in the amount of slip of a belt when it is transmitting different amounts of power. Doubts were originally expressed as to the possibility of such cones being used to transmit even 10-horse power satisfactorily, but their successful working having been proved, sets of them were reproduced for University College, Nottingham, the McGill University, Montreal, &c. This room contains many different types of dynamos, and, as space is limited, one is driven with a weighted pulley hanging in a very short belt passing over the fly-wheel of the engine, the dynamo itself being balanced on trunions, so that it turns on an axis at right angles to that round which the armature rotates.

The "injector" for producing any desired shape of wave, and so enabling one alternating current dynamo to serve the purpose of many, was shown in use, and the vibrating wire curve tracer, described at the last meeting of the British Association, was writing out the wave-forms so produced. The permeability of iron rods was being examined with the small dynamo recently shown at the Royal Society's soirée, and the regulation of transformers differentially tested with an electrostatic voltmeter, with which a pressure of one volt can be measured without any independent electrification.

Those interested in the bills sent in by Electric Light Companies had an opportunity of seeing American, English, French and German electric supply meters being tested at various temperatures in the Magnetic Research Laboratory, as well as experiments on the slow rise of temperature in underground electric mains.

The Electrical Research Laboratories contain various forms of electrostatic voltmeters, some of which were being tried, while others were in use for measuring the electric pressure at which cables and insulating oils break down by sparking. A Lorenz apparatus for the determination of the ohm, which had been constructed regardless of cost for the M'Gill University, and sent to the college to be tested, attracted much attention. It is certainly unique in its details, and eminently characteristic of the transatlantic millionaire who stipulates that the wealth which he showers on the laboratory named after him shall be used to purchase only the "very best apparatus." How many an English professor would delight in having such a condition imposed by a benefactor determined that the laboratory founded by him should be the most costly in the world.

In another room was a secohmmeter spinning out coefficients of self-induction, a new addition to the Wheatstone's bridge for facilitating the measurement of very small resistances, and an artificial submarine cable, electrically as long as those under the Atlantic, with which the retardation in the passage of the telegraphic signals was demonstrated to the visitors.

In the Arc Lamp Laboratories the photometry of the arc, and the steady feeding of the carbons with various types of lamps, were shown, also the details of the experimental lamp used in the recently published researches was explained. The observer sees close to him the arc itself and its image enlarged ten times, also the spots of light indicating the current flowing and the potential difference maintained between the carbons; while in front of him are handles for regulating the current, the position of each carbon, &c. Mark Tapley would doubtless have said that there was no credit in making discoveries under *such* circumstances.

On a screen on a wall the voltmeter and ammeter spots of another arc were seen dancing up and down, and proving that when an alternating current is superimposed on a direct current arc the oscillations of potential difference and current are in the same direction when the carbons are cored, but in opposite directions when they are solid.

Gas-burners and glow-lamp testing, polarimetry, and spectrophotometry are carried out in the Senior Optical Laboratory, and the curves of results obtained by the students showed the most economical gas pressure to use with each type of burner; why it pays the gas companies to make the gas flare and the private consumer to use governed burners, and how much dearer, as far as mere light is concerned, is glow-lamp lighting than gas lighting with the Welsbach burners.

A range of rooms on the first floor is devoted to the Junior Physical Laboratories, and in them students, who frequently have never worked in a laboratory before, learn the principles of electricity, heat, light, magnetism and sound by performing an organised series of quantitative physical exercises.

In both the Physical and Chemical Departments there were several exhibits of "seeing with X-rays," the potassium-platino cyanide screens, which have been so successfully constructed by Mr. Jackson, being lent for the occasion. The majority of the exhibits, however, in the Chemical Department were connected with the educational methods employed, and with the results which have been obtained from the researches carried out by the advanced students and the staff. Prof. Armstrong has long advocated that every student of chemistry should be early infused with the spirit of scientific inquiry; and that this principle has been practised in his laboratories, and not merely preached in his lecture-room, was proved by the large number of specimens of new series of compounds which were exhibited as the outcome of the work in his department. Sulphuric derivatives of camphor prepared for the first time in a pure state, hundreds of specimens of derivatives of naphthalene—the hydrocarbon from which so many modern dye-stuffs are made—obtained experimentally, and the apparatus for many researches in course of progress, attracted attention.

In the Junior Chemical Laboratory were exhibited the apparatus and experiments used in connection with the courses to teachers that have been given at the College. This apparatus is suitable for the use of teachers giving elementary instruction in technical schools, as well as for carrying out the experiments recommended in the syllabus of elementary science (chemistry and physics) issued by the Incorporated Association of Headmasters.

For the last ten years Dr. Armstrong has made strenuous efforts to obtain adequate recognition for that hitherto much neglected, but all important branch of physical chemistry, crystallography, and in consequence the crystallographic branch of the department has gradually extended in size, until at present the laboratory devoted to that subject rivals the best on the continent for completeness of equipment. Numerous measurements and drawings of crystals that had been made by the students were exhibited, and demonstrations of the methods employed in the optical examination of crystals were given in the adjoining lecture theatre during the evening, apparatus that had been specially devised to facilitate the accurate examination of doubly refracting substances being employed for the purpose.

In the Woodcarving Department, under the direction of Miss Rowe, there was an exhibition of carving in a variety of styles by present and past students, some of the latter being now the instructors in this and in other schools of art woodcarving. A renaissance panel illustrative of the arts of sculpture, architecture, and literature, an Italian bracket, and a pediment for a bookcase, a low relief renaissance frieze, &c., showed boldness and finish, while the practical demonstrations of the different

methods of working in high and low relief attracted much attention.

What is the outcome of it all, thought the visitor, as he left with his mind whirling with slotting machines, scalar quantities, secohmmeters, and sugar analysis? Has original research been prosecuted as foreshadowed by Lord Selborne? Where are the some 200 students that have been awarded the diploma of Associateship of the Institute, and all the other special students who have passed through courses at the Central Technical College? The seventy papers communicated by the students, and the staff, to the proceedings of various scientific societies answer the first question, while the reports issued yearly by the Dean give information on the second point; some of the past students are the Principals, and some have charge of departments at technical schools; some are the chief engineers and some assistant engineers at electric light central stations in England; some hold postsin chemical works, and some are railway engineers, and others telegraph engineers in India, but practically all appear to be employed. And what is a little remarkable—in view of the vast number of people who have been attracted to follow engineering pursuits during the past few years—we understand that nearly all the students who have passed through the Central Technical College are in receipt of pay for the services they are rendering, and are not paying premiums to employers for the privilege of being allowed to do hard work.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following is the speech delivered by the Public Orator, Dr. Sandys, in presenting for the honorary degree of Doctor in Science Prof. Newcomb, of Johns Hopkins University, Superintendent of the American Nautical Almanac.

Si Thales ille Milesius, "rerum naturae certissimus explorator et astrorum peritissimus contemplator," sapiens propterea nominatus est, quod solem lunae oppositu solere deficere primus omnium vidisse fertur, etiam hunc virum sapientiae laude non indignum arbitramur, qui solis et lunae defectus omnes antiquitus observatos cum astronomiae legibus hodiernis accuratissime comparavit. Idem quanto ingenii acumine aliorum de lunae motu placita correxit; quam admirabili studiorum caelestium cognatione cum Neptuni inventore nostro consociatus est; quam infinita denique cura fratribus nostris transmarinis trans aequora navigantibus siderum cursus litterarum monumentis mandatos explicavit. Talium virorum de genere humano merita dum contemplamur, non iam miramur ipsum Vergilium a Musis esse precatum, ut sibi ante omnia

"caelique vias et sidera monstrent,
defectus solis varios lunaeque labores."

Duco ad vos astronomum illustrem, SIMONEM NEWCOMB.

At the annual election, on June 22, at St. John's College, the Hutchinson Studentship was awarded to A. S. Hemmy, double first in Natural Sciences, for research in Physical Chemistry. Foundation Scholarships, varying in value from £100 to £50 a year, were given to the following Science Students:—K. C. Browning, D. J. Morgan, J. S. White, N. B. Harman, J. H. Howitt; and Exhibitions in Natural Science to J. A. Glover, R. F. C. Ward, A. C. Ingram, Jehu, and Yapp. In Mechanical Sciences and Engineering, Foundation Scholarships were for the first time awarded to W. S. La Trobe (£80) and A. Chapple (£50). It is noteworthy that Messrs. Hemmy, La Trobe, and Chapple, who have thus carried off the chief scientific honours, are all colonial graduates, from the Universities of Melbourne, New Zealand, and Adelaide, respectively. Mr. J. E. de Villiers, of this College, who takes the highest honours in Law, being senior in his Tripos Part I., is a graduate of the Cape of Good Hope.

The Harkness Scholarship in Geology and Palæontology is awarded to J. H. Gray, Scholar of King's College.

In Part I. of the Natural Sciences Tripos, thirty men are placed in the first class; in Part II. eleven men attain this distinction. No woman gains a first class in either part.

SESQUICENTENNIAL gifts continue to pour in upon Princeton University. An unnamed benefactor has given funds for a new library building.

THE following are among recent appointments:—Dr. Theodor Des Coudres to be Extraordinary Professor of Physics in Gottingen University, and Dr. Otto Bürger to be Extraordinary Professor of Zoology; Mr. A. A. Heller to be Instructor in Plant Taxonomy at the University of Minnesota, and Curator of the University Herbarium.

THE fitness of Convocation of the University of London to deal with such subjects as a Teaching University may be estimated from the result of the meeting held on Tuesday. The chief business was the election of a Fellow of the University, and the following gentlemen had been nominated:—Sir Joseph Lister, Mr. Walter Rivington, and Mr. Richard Mosey Stephenson. The election was one in which voting papers were permissible, and the result of the counting of the votes was that Mr. Rivington obtained 963, and Sir Joseph Lister only 846 votes.

THE report of the Technical Education Committee which was adopted at the meeting of the Devonshire County Council, held at Exeter on the 11th inst., shows that the work done on the agricultural side of Ashburton Grammar School is of so satisfactory a nature that an additional grant has been awarded to the school; also that 175 continuation schools have been maintained throughout the year. At the same meeting the following resolution was passed by a substantial majority:—"That this Council, while offering at present no opinion as to the advisability or otherwise of placing secondary education under the control of the local education authority, strongly deprecates the proposal to transfer to them any duties connected with elementary education."

A SPECIAL Committee, appointed by the West Riding County Council to watch the Education Bill, have passed the following resolution:—"That in view of the amendment to the Education Bill, 1896, whereby every non-county borough with a population of 20,000 is to appoint an Education Committee, amendments should be introduced by way of limiting the duties of the education authority of such a borough to such defined matters as may be least hurtful to the administrative county, and the cause of education."

A MEETING of the Executive Council of the County Councils Association was held on Friday morning last, at the Guildhall, Westminster. Lord Thring having briefly explained the circumstances under which the meeting had been convened, it was proposed by Lord E. Fitzmaurice, and seconded by Sir J. E. Dorington, Bart., M.P., and resolved:—"That this Council, considering the changes which have been introduced into the constitution of the education authority by the exclusion from the administrative county of non-county boroughs with a population of 20,000, is of opinion that the above change strikes a serious blow at the administration of the Technical Education Acts, and of county administration generally." It was also resolved that the Parliamentary Committee be authorised to arrange for the presentation of the foregoing resolution to the Right Hon. A. J. Balfour, M.P., and His Grace the Duke of Devonshire.

THE Education Bill has been abandoned by the Government, and the eleven days of Parliamentary time spent in discussing it have been sacrificed. It is proposed to bring up the subject afresh next January, but there is little possibility that the measure which will then be brought forward will be of the very contentious character of the one just withdrawn.

THE National Home Reading Union aims mainly to make high-class reading attractive, and to give advice with regard to courses of reading in romance, travel, biography, economics, ancient and modern history, English and foreign literatures, science and art. Once a year it is the custom of the Union to hold a summer assembly at some interesting centre, when lectures are given in connection with the courses of study which have been pursued during the past winter. This year Chester has been chosen, and the assembly takes place there between June 27 and July 6. But not only will the subjects recently studied claim attention, for there will be several lectures on the botany, geology, and architecture of the district, besides a lecture by Mr. St. John Hope on "The Arrangements of Mediæval Monasteries," with special reference to Chester. A number of interesting excursions and social gatherings have been arranged, including a visit to Northwich to descend a salt mine.

THE Technical Education Board of the London County Council next month will appoint not more than five Senior County Scholars. Each scholarship will be tenable for three years, and of the annual value of £60, together with free instruction in a college of university rank, provided that the fees

do not exceed £30 a year. In the case of scholars proceeding to the old universities a contribution of £30 per annum is made by the Board towards the college and university tuition fees. Candidates must be resident within the administrative County of London, and must send in applications to the Secretary of the Board, at 13 Spring Gardens, on or before Monday, June 29, on forms which can be obtained on application. Last year the Board awarded several exhibitions of smaller value to specially deserving candidates in addition to appointing five County Scholars. Hitherto the selection of the scholars has been based upon the record of their past achievements and testimonials received from their teachers or others qualified to judge of their capabilities. These scholarships are restricted to candidates whose parents are in receipt of not more than £400 per annum.

THE Hartley Institution at Southampton has not developed so much as it might have done since it was established, owing to a divided management and limited finances, but it has now entered upon a brighter part of its career, and we confidently expect to learn of rapid and vigorous growth in the near future. The Secretary of the Institution has retired on a pension, and the Town Council of Southampton have decided to grant a farthing rate for one year to the Hartley Council. The action of the Borough Council in giving rate aid in support of technical and scientific education, in addition to the whole of the residue under the Customs and Excise Act, shows that the friends of educational advancement upon the Council are strong enough to make headway in spite of contrary breezes. Dr. R. W. Stewart, the Principal, is now free to develop his well-laid schemes for extending and improving the work of the Hartley Institution, and there is every reason for believing that under his whole management, and with the increased resources now available, the Institution will extend in the right direction, while at the same time the position of Southampton as an educational centre will be advanced. The objects of the proposed reorganisation are, first, the extension of the evening technical classes, and, second, a complete change in the work of the day classes. The extension of the evening classes will take place mainly in improving and extending the trade and commercial classes, and in providing classes for teachers. It was to make these changes that a farthing rate was solicited. The help was asked not to relieve the Hartley Council of any present financial embarrassment, but to enable them to carry out a scheme of educational reform which must ultimately be of the greatest benefit to the town and neighbourhood. A few of the reasons which showed the necessity for reorganising the educational work of the Institution may be specified. The Institution is already provided with buildings, and during the last five years the accommodation and equipment had been greatly improved by the provision of new lecture-rooms, a chemical laboratory, a physical laboratory, and engineering and other workshops. All this would be practically wasted and lost to the town unless supplemented by the appointment of a properly qualified teaching staff, able to utilise and develop the resources of the Institution to the utmost. The income of the Institution—about £2750—was not quite enough to meet the general working expenses and to provide a staff of this kind; but with the grant now made by the Town Council a much more efficient return will be obtained. The development of the Institution on the lines suggested will enable students to obtain an education of university rank, and to proceed to a degree in arts, or science, or law, at the Uinversity of London, by attending a three years' course at the day classes of the Institution in their own town. Lecturers are to be appointed in mathematics, biology and geology, English and classics, French and German, at a salary of £150 per annum each. This is something for Southampton to be proud of, and we trust that the policy which has inaugurated the new epoch in the educational history of the town will permanently represent the feeling of the Borough Council.

SCIENTIFIC SERIALS.

American Journal of Science, June.—On the colour relations of atoms, ions, and molecules, by M. Carey Lea. Part II. If a coloured substance be formed by the union of a colourless kation with a colourless anion, the colour belongs to the molecule only. Consequently, if we find a solvent which, like water, is capable of separating the ions, the resultant solution when dilute must be colourless, no matter how intense the colour of the compound. Experiments confirm this law without exception. Antimony pentasulphide, a strongly coloured compound, is a case in point. When dissolved in an alkaline sulphide, the ions of antimony and sulphur, themselves colourless, separate sufficiently to no longer change each other's vibration periods. They still, however, remain within the sphere of mutual influence. The union of coloured and colourless ions gives rise to the most surprising changes of colour. Two similar coloured ions may unite to form a colourless element. Two similar colourless ions may unite to form a strongly-coloured element. No black ion is known. There is absolutely no relation traceable between the colour of an ion and that of the element which it aids to form.—The gravimetric determination of selenium, by A. W. Peirce. The usual method used in the gravimetric determination of selenious acid, that of precipitating the selenium with sulphurous acid in presence of hydrochloric acid, is slow and incomplete. The author substitutes potassium iodide for the sulphurous acid. To avoid obtaining the selenium in the pasty condition when large quantities are present, the potassium iodide should be considerably in excess of the amount necessary for precipitation.—The extinct *Felidæ* of North America, by G. I. Adams. This is an attempt to give a general account of this family, to summarise the literature on the subject, and to work out a comprehensive classification. The paper is accompanied by three admirable plates.—The age of the igneous rocks of the Yellowstone National Park, by Arnold Hague. The pouring out of igneous rocks began with the post-Laramie uplift, or closely followed it, and from the time of the first appearance of these rocks, volcanic eruptions continued throughout Tertiary time.—Researches on the Röntgen rays, by Alfred M. Mayer. Herapathite, an iodosulphate of quinine, the most powerfully polarising substance known, is incapable of polarising X-rays. The actinic effect of X-rays varies inversely as the square of the distance of the sensitive plate from the radiant source.—On the *Pithecanthropus erectus*, from the Tertiary of Java, by O. C. Marsh. It may be taken as established that the remains of this "missing link" at present known are of Pliocene age. The tooth, skull, and femur found belonged to the same individual. This individual was not human, but represented a form intermediate between man and the higher apes.

Wiedemann's Annalen der Physik und Chemie, No. 5.—Anomalous electric dispersion of liquids, by P. Drude. Short electric waves (of 70 cm wave-length in air) are more strongly damped in alcohol, and especially in glycerine, than in water or in aqueous solutions. Theoretically, the damping should increase with the conductivity. But these badly conducting bodies are found to damp electric waves as effectually as a 5 per cent. solution of copper sulphate, which is 6000 times more conducting. This is not the only anomaly exhibited by ethyl and amyl alcohol, glycerine, and acetic acid. They also show anomalous dispersion for rapid electric oscillations, *i.e.* a decrease of the electric index of refraction with increasing frequency. Further, the specific inductive capacities are greater than the squares of the electric indices of refraction. Water, methyl alcohol, and benzol show no such anomalies, and ether only shows anomalous absorption.—Thermo-couples of amalgams and electrolytes, by A. Hagenbach. These were prepared by connecting two beakers filled with an amalgam by means of an M-shaped siphon filled with an aqueous solution of a salt of the same metal, the ends of the siphon being closed by a membrane. The amalgams were enclosed in water baths, and could be heated simultaneously or alternately. The only metals suitable for accurate measurements were cadmium and lead. Theory demands that as the salt solutions are diluted the thermo-electric forces shall increase. This law was found to fail with the divalent elements named. A couple, consisting of cadmium amalgam and cadmium chloride or nitrate, showed a steady diminution of the thermo-electric force as dilution increased from 0·1 to 0·0001 of the normal.—Contributions to the knowledge of fluorescence, by G. C. Schmidt. The author maintains that all bodies are capable of fluorescence if dissolved in suitable solvents. The most favourable form in which a substance may occur is that of a "solid solution." Aniline dyes may be made to fluoresce by solution in sugar, gelatine, hippuric acid, quinine bisulphate, and other substances. The colour of fluorescence is often nearly independent of the solvent.—Theoretical investigations concerning light, by P. Glan. The author calculates the absorption of various substances for a certain kind of ultra-violet light from their thermal conductivities and refractive indices, and shows that muscle, horn, wood, bone, cork, paper,

ebonite, shellac, lampblack, water, and carbon bisulphide must behave towards these rays in the same manner as they have been found to behave towards Röntgen rays.—A new form of mercurial air-pump, and the preservation of the vacuum in Röntgen tubes, by R. W. Wood. The author describes a simple pump consisting of a system of tubes and bulbs containing the vacuum tube in one branch. It is completely closed, and the vacuum is restored at will by simply oscillating the whole apparatus.

Bulletin de la Société des Naturalistes de Moscou, 1895, No. 2.—Contributions to the knowledge of the molecular forces, as a foundation to thermodynamics, by J. Weinberg; fourth part, dealing with capillarity and adhesion.—The development of the occipital region of the lower verterbrates, in connection with the question of metamery of the head, by A. Sewertsoff. An elaborate and suggestive work, in German, with two plates.—On the rotation of the earth, supposed to be fluid in its interior, by Th. Sloudsky, in French.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 4.—"Observations on Atmospheric Electricity at the Kew Observatory." By Dr. C. Chree.

The primary object of the investigation was to arrive at a more exact interpretation of the records obtained with the Kew electrograph, and to devise improvements in the conditions under which it works. The electrograph curves are intended to give the value of the potential at the point in the air where a water jet issuing from a long pipe breaks into drops. The proximity of a tall building has naturally, however, a large influence on the potential, so that no direct estimate could be made of the true potential gradient, *i.e.* the increase in potential per unit of height in the open.

Some preliminary experiments were made, which may be regarded as verifying Prof. Exner's experimental conclusion that a building under normal conditions reduces the potential in its neighbourhood, as if it formed an integral part of the earth's surface. Subsequently four series of observations were made. The respective seasons were November–December, 1894, March–April, June–July, and October–November, 1895. The observations were taken with a portable electrometer of known scale value, at one or two approximately constant hours, at five or six stations on or near the Observatory.

The results were consistent with the view that such general phenomena as diurnal or annual variation of potential got out with the same instrument at the several stations would show a good agreement.

A comparison was also made between the potentials deduced from the electrograph curves and the readings of the portable electrometer.

The values of the several meteorological elements, at the times of the observations with the portable electrometer, were derived from the Observatory records.

They afforded the opportunity of carrying out a searching investigation into possible connections of the several meteorological elements and the potential gradient. Attention was particularly directed to data bearing on Exner's theory, which connects potential gradient with density of aqueous vapour through a definite formula, departures from which are to be regarded as abnormal and due to disturbing causes. Special attention was also devoted to the possible influence of bright sunshine in reducing the potential gradient, in consequence of the theory proposed by Elster and Geitel.

The results of the investigation seem far from favourable to Exner's hypothesis. They afford a certain amount of general support to Elster and Geitel's theory, inasmuch as on an average potential seemed lower after long previous sunshine. The evidence, however, in favour of a connection between high potential and low temperature, high barometric pressure, low wind velocity, and anti-cyclonic conditions generally, seems about equally strong with that in favour of Elster and Geitel's theory. In each case notable exceptions appeared to any general rule.

Chemical Society, May 28.—Mr. A. G. V. Harcourt, President, in the chair.—Prof. P. P. Bedson delivered the Lothar Meyer Memorial Lecture. The lecturer reviewed Meyer's contributions to our knowledge of the gases contained in the blood and of the periodic law, and gave an account of the work done by the late German chemist towards promoting the systematic arrangement of inorganic chemistry, pointing out how great had been Meyer's influence on the promotion and advancement of chemical theory during the past thirty years.

June 4.—Mr. A. G. V. Harcourt, President, in the chair.—It was announced that an address is to be presented to Prof. Cannizzaro on the occasion of his seventieth birthday in July next; an address is also being presented to Lord Kelvin on the completion of his fiftieth year as Professor of Natural Philosophy in Glasgow University. The following papers were read:—On magnetic rotatory power, especially of aromatic compounds, by W. H. Perkin. The author describes apparatus used for determining magnetic rotations, and having determined the influence of temperature and dissolution on this property, gives the results of the examination of a large number of compounds of different types. Great differences exist between the magnetic rotations of aromatic and fatty compounds, the nuclei contained in a substance considerably influencing its rotation; frequently the compounds behave as composite molecules, the fatty and cyclic part separately influencing the magnetic rotation; the presence of a carbonyl group connecting the nucleal and fatty groups seems to act as a screen, preventing them from influencing each other. The influence of the nucleus on the rotation is reduced by the presence of electro-negative groups, and increased by that of electro-positive ones; this great liability of the magnetic rotation of the nucleus to change, is connected with the fact of its unsaturatedness, for saturated cyclic compounds behave like ordinary open chains. The so-called values given for atomic refractions or magnetic rotations are not true physical constants, but are merely the average influences which elements or radicles exert in different compounds; this, however, does not detract from their usefulness in determining constitution.—Mononitroguaiacol, by R. Meldola. One mononitro-derivative, probably the para-compound, is obtained by nitrating acetylguaiacol; benzoylguaiacol yields two mononitro-derivatives, probably the ortho- and para-, on nitration. Mononitroguaiacol may be prepared by hydrolysing its acetyl-derivative.

Linnean Society, June 4.—Anniversary Meeting.—Mr. C. B. Clarke, F.R.S., President, in the chair.—The Gold Medal of the Society was formally awarded to Prof. G. J. Allman, F.R.S., for distinguished researches in zoology, and, in consequence of his inability to receive it in person, was delivered on his behalf to Sir Joseph D. Hooker, K.C.S.I., who made a suitable acknowledgment. The Treasurer then presented his annual statement of accounts. The Secretary reported the deaths, withdrawals, and elections during the past year. The report of the Librarian having been read, the President opened the chief business of the evening, when the Fellows present proceeded to ballot for the President, Officers, and Council for the ensuing year. Scrutineers having been appointed, and the votes counted, the result was declared to be as follows:—President, Dr. Albert Günther, F.R.S.; Treasurer, Mr. Frank Crisp; Secretaries, Mr. B. Daydon Jackson and Prof. G. B. Howes. The retiring President, Mr. C. B. Clarke, then delivered the annual presidential address, which on the motion of Mr. W. Carruthers, seconded by Mr. W. P. Hiern, it was resolved should be printed and circulated.

Mathematical Society, June 11.—Major MacMahon, R.A., F.R.S., President in the chair.—The Chairman announced that the Council had awarded the De Morgan Memorial Medal to Mr. S. Roberts, F.R.S. He also read an address which the Council had requested him to present to Lord Kelvin on the occasion of the jubilee celebration on the 16th instant. The address, which was illuminated, was placed for inspection on the table. The following communications were made:—Waves in canals, by H. M. Macdonald; on the *a*, *b*, *c* form of the binary quintic, by J. Hammond; construction for the four normals to a central conic drawn through a given point, by Prof. Mathews; on a two-fold generalisation of Stieltjes' theorem, by Dr. Taber; notes on magic squares, by Rev. A. H. Frost.

Entomological Society, June 3.—Dr. D. Sharp, F.R.S., Vice-President, in the chair.—Mr. Gervase F. Mathew exhibited the new species of Leucania, *L. flavicolor*, recently described by Mr. Barrett (*Ent. Monthly Mag.*, 2nd series, vol. vii. p. 99), and also the varieties of *L. pallens* noticed by Mr. Barrett in the same article (*l. c.*, p. 100). Mr. Tutt having carefully examined the specimens of *Leucania flavicolor*, said that he considered it

as highly probable that it was a remarkable form of *Leucania pallens*, but that more material was required before a final opinion could be formed. The remarkable transverse (elbowed) line of dots crossing the forewings was exactly parallel with that of *Leucania straminea* and *L. impura* ab. *punctalinea*, and for an aberration of this character to occur in *L. pallens* was as probable as in *L. impura*, the typical form of which is but sparingly dotted in the direction of the elbowed line. The hindwings showed almost identically the same characters in the dark shading, traces of dots in nervures, &c., as the red aberrations of *L. pallens* exhibited by Mr. Mathew. He considered that until the matter of its specific distinctness was finally settled, Mr. Barrett had erred on the right side in giving it a distinctive name, even if the name subsequently fell as an aberration of *L. pallens*.—Mr. Waterhouse exhibited several branches of oaks from the New Forest entirely denuded of foliage, and stated that throughout large tracts of the forest the oaks had been stripped of their leaves in the same fashion by Lepidopterous larvæ, especially *Cheimatobia brumata*, *Hybernia defoliaria*, and *Tortrix viridana*. Certain trees, however, though situated among the denuded trees, had quite escaped. Dr. Sharp suggested that they belonged to a different species; but Mr. Waterhouse said that he had carefully examined them, and that this was not the case. Mr. McLachlan said that the immunity of the trees referred to was probably due to irregularity in coming into leaf. —Mr. Tutt exhibited living pupæ of *Enodia hyperanthus* and *Epinephele ianira*, and pointed out how different the pupæ of these two species were in general appearance, structure, and cremastral attachment from each other. He pointed out that these two species had for a long time been erroneously placed in the same genus, but that, in all stages, they were widely separated, and that not only should they be placed in different genera, but that they appeared to belong to different tribes—*Enodia hyperanthus* being in the *Cœnonymphidi* and *Epinephele ianira* in the *Epinephelidi* (*vide Entom. Record*, vii. p. 301).—Mr. Blandford exhibited and described series of tropical American butterflies from the Godman-Salvin collection, arranged to show the existence and geographical distribution of homœochromatic groups.—Dr. Chapman communicated a paper on the phylogeny and evolution of the Lepidoptera from a pupal and oval standpoint.

Geological Society, June 10.—Dr. Henry Hicks, F.R.S., President, in the chair.—On foliated granites and the relations to the crystalline schists in Eastern Sutherland, by J. Horne and E. Greenly. The crystalline schists of Eastern Sutherland are traversed by great numbers of granitic intrusions, chiefly in the form of lenticular sills. These generally lie parallel to the foliation-planes of the schists, but transgressive junctions are also frequent. Thin seams of granite also occur in such abundance as to constitute with the schists a banded gneissic series; but these seams can often be seen to transgress the schistose folia, and even often to proceed from large masses of granite. The granites contain numerous inclusions of the schists which they traverse, such inclusions retaining, usually, the dip and strike of the surrounding rocks. There are no chilled edges; and, moreover, the component crystals of schist and granite mutually interlock along the line of junction. The authors gave an account of the foliation of the granite. In some rare cases a foliation parallel to that of the schists traverses granite-veins. It is generally, however, parallel at once to the sides of the sill and to the foliation of the schists; and many of the structures are the remains of biotite folia belonging to schists whose quartzo-felspathic elements have been incorporated with those of the granite. But many sills or veins, traversing the schists at various angles, are foliated parallel to the line of junction, and so discordantly to the structures in the schists; and foliated granites may even be observed to cut each other's foliation. These can hardly be anything but original igneous structures; but, if coexistent with the last-named, would be indistinguishable from it. The country-rocks are various types of biotite-schist or gneiss, with quartz-schists at Kildonan, and a scapolite-limestone at Armadale. They are almost all holocrystalline, but it is certain that sedimentary rocks enter into the complex. The whole series is powerfully folded. The granites increase in size and numbers north-westward from Kildonan; the intimate intrusive relations above described becoming more highly developed in the same direction. The schists, at the same time, become more and more highly crystalline, sillimanite also appearing in them. About Kinbrace they are coarse sillimanite-biotite-gneisses, with large striated felspars. Igneous contact was not held to be the sole origin of metamorphism, though the cause which brought about the introduction of the granites had evidently also produced these high types of crystallisation. The evidence of powerful movement which the schists everywhere present suggested that such movement was the initial cause of the whole series of phenomena. Movement recurred throughout, though all cataclastic structures (if such existed) had been wholly effaced by crystallisation; introduction of granite being the final stage in the production of the complex, and a high temperature (as shown by the absence of chilled edges) being maintained to the very end. With regard to the granites, the authors found it difficult to believe that they are wholly foreign matter, but remark that it is necessary to observe the utmost caution with reference to it.—The geology of the eastern corner of Anglesey, by E. Greenly.—Seismic phenomena in the British Empire, by M. F. de Montessus de Ballore, Captain of Fortress Artillery at Belle-Ile-en-Mer. The author gave a brief outline of a plan that he has elaborated for studying seismology. He has separated his work into four parts: (1) The formation of an earthquake catalogue. (2) Refutation of the empirical laws previously ennuciated. (3) Description of the globe from a seismological point of view. (4) Investigation of the characters which differentiate stable from unstable regions. He gave a method by which the relative *seismicity* (or instability as regards earthquakes) of regions may be obtained and registered, and indicated some of the results which he had derived from his study, including the intimate relationship between instability and surface-relief, and the independence of seismic and volcanic phenomena. The main part of the paper was a section of the third division of the author's work, and dealt in detail with the earthquakes of the British Empire. In this part of the paper, the recorded earthquakes of the British Isles, India, Australia and New Zealand, British Africa, Canada, and various scattered possessions were described.

EDINBURGH.

Royal Society, June 15.—Prof. Geikie in the chair.—Mr. A. T. Masterman read a note on the structure of *Actinotrocha* considered in relation to the chordate affinities of *Phoronis*. In this paper, the author demonstrated the presence of a paired notochord in *Actinotrocha* which atrophies before the adult stage is reached, probably at the metamorphosis. He also showed the presence of five body-cavities in the larval stage. For these and other reasons he claimed for *Phoronis* a place among the Chordata, and proposed to place it in a separate division of this group—the Diplochordata. The relationship of *Phoronis* to *Balanoglossus* may be compared to that of the *Tunicata* to *Amphioxus*.—Prof. Tait read a paper on Clerk-Maxwell's law of distribution of velocities in a group of equal colliding spheres. He adverted to the extraordinary denunciation by M. Bertrand of Clerk-Maxwell's proof of the fundamental law of the kinetic theory of gases. He showed that Maxwell's proof involved none of the absurdities alleged by M. Bertrand, and that the gist of the matter was this:—There is a *unique* solution of the problem: Maxwell's is *a* solution, because it is not interfered with by collisions; therefore it is *the* solution.—Prof. Chrystal gave a summary of a paper on the p discriminant of a differential equation of the first order, in which he applied Newton's method of approximation (first employed in the theory of differential equations by Briot and Bouquet) to prove some leading theorems regarding the p discriminant locus, most of which had previously been established by Darboux by other methods. He showed that the p discriminant locus (A), $\phi(x, y, p) = 0$, $\phi_p(x, y, p) = 0$ is, in general, a cusp-locus for the family of integral curves. He also established that the locus, $\phi(x, y, p) = 0$, $\phi_x(x, y, p) + p\phi_y(x, y, p) = 0$, is in general an inflexion-locus (B), and that $\phi(x, y, p) = 0$, $p\phi_x(x, y, p) - \phi_y(x, y, p) = 0$ is a locus of inflexions on the orthogonal trajectories of the integral family (C). Any point of intersection of A and B, is, in general, a point at which two integral curves touch each other, and also touch A. The necessary and, in general, sufficient condition for an envelope singular solution is that A and B have a branch in common. The necessary and, in general, sufficient condition that two integral curves touch, and do not touch A, is that A, B, C have a point in common. The necessary and, in general, sufficient condition for a tac-locus is that A, B, C have a branch in common; the characteristic of this branch appears as a squared factor in the p discriminant. Prof. Chrystal then proceeded to refute a proposition of Cayley's, "that a differential equation of the first

order, which has no singular solution, cannot have an algebraic integral." He showed that Cayley's proof that every algebraic family has a proper envelope, on which this conclusion regarding differential equations depends, fails to take account of the fact that the residual points of intersection, $m + n$ in number, may be concentrated in isolated points, usually tac-points; and produced examples of cubic and quartic families which, in point of fact, have no proper envelope.—Prof. Ewart gave a summary of a paper by Mr. Frank J. Cole, on the cranial nerves of *Chimæra monstrosa*, with a discussion of the lateral line system, and of the comparative anatomy of the chorda tympani nerve.

PARIS.

Academy of Sciences, June 15.—M. A. Cornu in the chair.—Formula for the mean local pressures in a fluid moving irregularly or in vortices, by M. J. Boussinesq.—On the variations observed in the composition of apatites, by M. Adolphe Carnot. In Canadian apatites some of the calcium fluoride would appear to be replaced by calcium carbonate without change of crystalline form. In some apatites from the Tyrol, which presented the crystalline properties of normal apatite, the amount of calcium fluoride is reduced to about one-tenth of that usually present.—On the presence of *Campodea staphylinus* (Westwood) and *Sabacon paradoxus* in the cave of Dargilan (Lozère), by M. Lannelongue.—Remarks on the preceding communication, by M. E. Blanchard.—On the value as food of bread from different specimens of screened flour, by M. A. Girard. From a comparative study of the amounts of phosphorus in various samples of bread, the conclusion is drawn hat there is no real justification for the use of brown bread in preference to white, when the digestive organs are in a healthy state.—Observations and remarks on the bactericidal power of blood serum, and on the bactericidal substance contained in it, by M. S. Arloing. The experimental results obtained do not appear to sustain the idea of a specific substance in the serum of bactericidal properties. It was found that solutions of many salts could replace the solution of common salt as a diluent of the serum without appreciably affecting its action upon bacteria.—Measurement of the work expended in driving a bicycle, by M. Bouny. The work done was measured by a pedal of special construction containing two dynamometers, arranged so as to register the force exerted in two directions at right angles to each other, and also so as to take into account the effect produced by the deviations of the pedal from the horizontal plane. The work done by the pressure on the pedal is given as a function of the speed. To double the velocity (17 to 33 kilometres per hour) more than trebled the work required to be done.—Remarks on the preceding communication, by M. Marey.—On apsidal surfaces, by M. A. Mannheim.—On the theorem stated by M. P. H. Schoute in the *Comptes rendus* of May 18, by M. D. J. Korteweg. A simplification of one part of the demonstration of this theorem.—On the note of M. P. H. Schoute, entitled "The area of parabolas of higher order," by M. G. Mannoury.—On the method of least squares, by M. Jules Andrade.—On multiple resonance of electric oscillations, by M. Nils Strindberg An experimental study of the theory of MM. Poincaré and V. Bjerknes on the phenomena of multiple resonance, discovered by MM. Sarasin and De la Rive. By the use of a new form of electro-dynamometer based upon the Joule effect, it has been found possible to determine completely the form of the curves of interference. Qualitatively, the results obtained verify the above theory.—Non-isotropic magnetisation of crystallised magnetite, by M. Pierre Weiss. From the fact that magnetite crystallises in the cubic system, complete symmetry of magnetic properties in all directions might be expected. The experiments detailed, however, show that this is not the case.—On the surfusion of water, by M. J. Passy. It is possible to produce a precipitate in surfused solutions without causing crystallisation to begin.—On the diurnal variation in rain, by M. A. Angot. In summer the maximum amount of rain at Paris falls between 3 p.m. and 6 p.m. In winter the maximum, which is not so well marked, appears to be between 6 a.m. and 9 a.m. In March, April, October, and November there is no appreciable daily variation.—Dissociation spectra of fused salts. Alkali metals: sodium, potassium, lithium, by M. A. de Gramont.—On the reproduction of colours in chromotypography, and on a simple system of colour notation, by M. Steinheil.—On a reaction of cuprous compounds serving as a characteristic test for nitrites, by M. Paul Sabatier. A solution containing a nitrite, treated with concentrated sulphuric acid and a little cuprous oxide, gives a characteristic violet colouration.—On the zirconotungstic compounds, by M. L. A. Hallopeau.—Synthesis of natural methylheptenone, by MM. Ph. Barbier and L. Bouveault.—Contribution to the study of the anterior region of the digestive apparatus of the higher Stenoglossia, by M. A. Amaudrut.—Artificial reproduction of a chlorocarbonate of sodium and magnesium, and a double carbonate of the same bases. Artificial reproduction of darapskite and hydrargylite, by M. A. de Schulten.—On the rare minerals of the glacier of Meije, by M. A. Lacroix. The minerals include anatase, brookite and turnerite.—Chalk containing hippurites of the eastern province, by M. H. Douville.—On the presence of a genus allied to *Caprina* in the limestone at Chateauneuf-du-Rhône (Drôme), by M. V. Paquier.—On the relations between thermal sensibility and temperature, by M. C. Henry.—Action of the porcelain filter upon snake venom; separation of the toxic substances and vaccinal substances, by M. C. Phisalix.—On some derivatives of diphenylethylene diamine, by M. C. Gassmann.—Studies on peridinitronaphthalene, by the same.—On a method of observing sun-spots, by M. Bougon.

CONTENTS.

THURSDAY, JULY 2, 1896.

THE CELL-THEORY.

Leçons sur la Cellule Morphologie et Réproduction faites au Collège de France pendant le semestre d'hiver 1893–94. Par Félix Henneguy. Pp. xix + 541. 362 figures. (Paris: Georges Carré, 1896.)

THE cell occupies, and has for half a century occupied, so important a position in biological science, that the literature dealing with it and the number of general works called up by this literature has become enormous, and is daily increasing. Nor is this a matter to be wondered at, for the subject is one of supreme importance to the biologist, and contains within its border the very innermost mysteries of life. But in saying this, we do not wish to be understood as giving our adhesion to this or to that modern school of thought with regard to the importance of the cell in organisms. It is sufficient for us to note the fact that, great as has been the influence of the conception of cell on biological investigations in the last fifty years, the chief merit of the founders of the cell-theory lay less in giving us that conception than in fixing attention upon the matter of which the organism is composed. To the cell-theory we owe our conception of the organism as a body composed of protoplasm—the real living matter, and of formed material—the non-living or semi-living framework. The former is the true seat of life, and the latter is produced as a result of its vital activity. This conception has been an analytical tool of the most powerful kind, and has assisted very considerably in the task of unravelling the complexity of structure and function of the parts of organisms. The cell-theory first fixed our attention upon protoplasm, and upon that most important part of protoplasm the nucleus; and it is to the study of protoplasm and of the nucleus, of their structure, relations, and activities, that the great advances in modern biology are due. This, we repeat, was the great work of the founders of the cell-theory. But they did more than this: they first showed us that the living substance is often arranged in and works through small structural units called cells; and they first gave us the idea that the organism is composed of independent or semi-independent individuals associated together in a colony for the common good. It is this idea, this hypothetical explanation of cellular structure, which constitutes the cell-theory; and it must be clearly borne in mind that the promulgation of this hypothesis was the least important part of the work of the founders of that theory. At the same time it is an undeniable fact that this hypothesis was held, and indeed is held largely at the present day; and that it has had a most important influence upon biological research. Of its value we express no opinion, but we should be wanting in our duty if we did not point out that of late years a slowly increasing number of biologists have cast doubts upon its validity and utility as an explanation of cellular structure, and are content to hold for the present that cellular structure has not received any adequate explanation, or, to use the somewhat vague words of Sachs, is a phenomenon of secondary significance, and merely one of the numerous expressions of the formative forces which reside in all matter, and in the highest degree in organic substance.

It is obvious that a work dealing with the cell in this wide sense, viz. as an equivalent for protoplasm and nucleus, must have a very large scope indeed; for if complete, it would include the whole of vegetable and animal histology and physiology. Owing to human limitations, it is in these days impossible for a single author to take this wide outlook, and we find in works dealing with the cell restrictions of various kinds. As a general rule, an author will limit himself to animal or to vegetable protoplasm, and a full consideration of the formed material is nearly always excluded. The part of the subject to which special attention is devoted—at any rate in recent works—is the structure of protoplasm, and of the nucleus and the behaviour of the nucleus in division and in conjugation. M. Henneguy is not content with any restriction of this kind, and though modestly disclaiming all idea of giving a complete account of the subject, and of having written a treatise on Cytology, he has in our opinion produced a more complete work on protoplasm and the nucleus than any of his predecessors. The work represents a course of thirty-one lectures given at the College de France in the winter of 1893–4, and is an admirable account of the state of our knowledge to that date. The author deals both with animal and vegetable protoplasm, with its chemical and physical constitution, with its structure, with the nucleus, the change which it undergoes and its relation to the cytoplasm, and with its division and its conjugation. An account of the nutrition of the cell, of the products of cellular activity, and of its functional differentiation, occupies a prominent place in the work. Finally he has a chapter on the relation of cells to each other, and another on the most important hypotheses on the constitution of protoplasm, and he begins the work by an excellent account of the growth of knowledge on the subject.

The work is of course a didactic one, and in no sense is to be regarded as an original contribution to knowledge. The author's object is to give an account of the facts which have been definitely established, relegating to the second place controversial or doubtful matters.

And in this he does well, for, as he points out, the tendency at the present day among a certain class of small workers to premature publication and to hasty generalisation, leads to most disastrous results in the accumulation of third-rate literature. A single fact, which often turns out to be no fact at all, is hidden in pages of raw and worthless speculation. "Another cause assists in accentuating this pernicious tendency. In certain schools far too much emphasis is laid upon new and still controverted observations, and classical works confirmed by numerous and reiterated observations are too often neglected, and future observers thus deprived of a sure and solid basis." He devotes a special section to the consideration of the effects of the different kinds of reagents used by histologists in altering the structure of protoplasm, and he calls the attention of his readers to the importance of the study of living protoplasm, and of checking all their results by it. This is a most important point, too often lost sight of in the rush and petty

ambition of modern laboratories, and one which cannot be too strongly impressed on young workers.

The author's treatment of that most important subject of protoplasmic fusion is not entirely satisfactory. He distinguishes two kinds: (1) fusion in which several cells unite to form a multinucleated mass, as in the *Mycetozoa* and some *Rhizopoda*; (2) conjugation, in which two or more cells fuse to form one cell; the distinction being that while in the latter case the process is accompanied by nuclear fusion, in the former it is not. In the first place it must be noted that conjugation does not always result in the formation of one cell from two, *e.g.* many ciliate infusoria; and in the second, that it is by no means certain that nuclear fusion does not occur between the nuclei of the multinucleated masses resulting from fusion. Moreover the author falls into the common error, found even in some of the best text-books, of calling conjugation a mode of reproduction. On p. 416 he says, "J'arrive maintenant à une mode spécial de reproduction, cellulaire que nous connaissons déjà, à celui que nous avons désigné sous le nom de *conjugaison* et que nous avons distingué de la *fusion*." It is perhaps hardly necessary to point out that by reproduction the number of individuals of a species is increased, while by conjugation it is generally diminished. It is true that conjugation results in the formation of a new individuality, but not in the increase in the number of individuals.

It is hardly going too far to say that conjugation is the opposite of reproduction. It is curious that this mistake should so often be made, and it is most important to call attention to it; for the confusion between the two processes, which has no doubt resulted from their accidental association in sexual reproduction, has considerably interfered with the proper appreciation of that most mysterious and important of vital processes—fusion of nuclei and protoplasm.

With regard to technical terms, we may be allowed to call attention to our author's use of the word *Cytodieresis*. He proposes this word for the process of cellular division, which is accompanied by those characteristic transformations of the nucleus which are ordinarily termed karyokinetic, reserving the word *division* for those cases in which the nucleus divides directly. We do not inquire whether such a word is required, but we desire to point out that on the very next page (296), our author uses the word Cytodieresis as the equivalent of *Caryodieresis* (indirect nuclear division). He says: "*Division indirecte* (of the nucleus) = *karyokinesis* (Schleicher) = *cytodieresis* (Henneguy) = *mitosis* (Flemming)." The looseness of thought implied by this confusion in the use of his own word is unsatisfactory, and would by some biologists be pointed to as an example of the result of too strongly holding to a theory which does not conform with all the facts.

In criticising Weismann's suggestion that the Protozoa are immortal, he says that "a Protozoon which divides dies in the sense which we attach to the death of the higher animals, *i.e.* that its individuality disappears." Though we are quite willing to admit that Weismann's statement was more of the nature of a gallery phrase designed to catch the ear of the readers of the modern magazine article, than a serious contribution to science, and that it conveyed no new idea or suggestion, we cannot follow M. Henneguy in his criticism quoted above. For do not the higher animals also undergo numerous successive divisions in the production of their reproductive cells, which differ in no essential particular from the successive binary fissions which a Paramœcium passes through in its life-history. The only difference which can be pointed to is one merely of degree; for there is no more an absolute similarity between the two products of fission in an infusorian than there is between the products of the fission (ovum or spermatozoon and parent) which is continually taking place in the higher animals. You might just as reasonably assert that a hen dies whenever it lays an egg, as make the statement that a Paramœcium dies at each process of fission. With the words death and individual a philosopher can do much; but it behoves practical men to keep a sharp look-out on the use made of those convenient terms.

The book is well printed and illustrated; and though it is not a complete and carefully elaborated treatise on protoplasm, as the author himself is the first to admit, yet it constitutes a valuable addition to the biologist's library, and cannot fail to be of great use to the teacher as well as to the student.

A ROMANTIC NATURALIST.

From North Pole to Equator, Studies of Wild Life and Scenes in many Lands. By the Naturalist-Traveller, Alfred Edmund Brehm. Translated from the German by Margaret R. Thomson. Edited by J. Arthur Thomson, M.A., F.R.S.E. (London: Blackie and Son, Ltd., 1896.)

"BETWEEN North Pole and Equator" might have been a less attractive, but would have been a more accurate title for this book, for Siberia and northern Norway are not as far north as the Pole, nor are Nubia and the Blue Nile as far south as the Equator. Between these limits, however, the late Dr. A. E. Brehm made extensive journeys, visiting most of the principal types of country that may be found therein, and studying the characteristic faunas with the enthusiasm of a born naturalist. His great "Thierleben" is a rich repository of information on the habits of animals, the various groups of which are taken in zoological order. The present book appears to be intended as a supplement to this; for it is geographical in arrangement, and consists of a series of graphic sketches of wild life in many lands.

The work opens with a brief homage to the author by his son, and then an admirable introductory essay by the editor upon the work of naturalist-travellers in general, and of A. E. Brehm in particular. Mr. Thomson gives a list of works by English naturalist-travellers, in which we notice Fred Burnaby's "Ride to Khiva," although such books as Lamont's "With the Sea Horses," Butler's "Great Lone Land," and Whymper's "Travels among the Andes of the Equator," are not mentioned.

Mr. Thomson classifies naturalist-travellers into five groups—the Romantic (including Sir John de Maundeville and other mediæval story-tellers); the Encyclopædists of the sixteenth and seventeenth centuries; the General Naturalists, ranging from Ray to Humboldt; the Specialist Type—the naturalists of the naval expeditions

of the present century; and the Biological Type, such as Darwin, Wallace, and Bates. Mr. Thomson includes Brehm in the last group; but if we accept his definition of the Romantic Type (p. xvi.), Brehm has certain claims to be placed among these. "In days when the critical spirit was young," Mr. Thomson tells us, and "verification hardly possible; there could not but be a strong temptation to tell extraordinary 'traveller's tales.' And they did. Nor need we scoff at them loudly, for the type dies hard; every year such tales are told." We have only to turn to p. 38 to see a proof of this. There we learn that in the fiords of northern Norway "the fish swim so thickly that the boat has literally to force a way among them, . . . that an oar placed upright among the densely-packed crowd of swimmers remains for a few moments in its position before falling to one side." Or on p. 83, where we are told that in the tundra "every grass-stalk, every moss-blade, every twig, every branch, every little leaf sends forth hundreds and thousands of them [mosquitoes] all day long." After this we are prepared to learn that the mosquitoes "form swarms which look like thick black smoke; they surround, as with a fog, every creature which ventures into their domains: they fill the air in such numbers that one hardly dares to breathe; they baffle every attempt to drive them off; they transform the strongest man into an irresolute weakling, his anger into fear, his curses into groans." These are samples of the author's style, and of the precision of his descriptions. His book is written in superlatives, which appear to be laboured, and is full of humour, which is generally unintentional. But in spite of the author's command of impressive language, he is very modest; the heat of Africa, he tells us, is "indescribable," and then does his best in a page full of sentences, such as the following. "The torments are inconceivable." "Nor can any one who has not groaned through these nights, when one tosses on the couch, prevented by the sultriness from resting or sleeping, adequately sympathise with the torments to which men and animals are subjected at this season." "Men and beasts seem to wither as the grass and leaves withered." "In vain does manly courage endeavour to bear up under the burden of these days; the most resolute will give way to sighs and moans. Every piece of work fatigues, even the lightest covering is too heavy, every movement is an effort, every wound becomes a virulent sore." After this we are not surprised to find an account of a tropical thunderstorm and its effects, written in language that reads like an American journalist's report of the Johannesburg dynamite explosion; and that, in escaping the steppe fires, "antelopes, zebras and ostriches speed across the plain more quickly than the wind"; or that a view of the baobab is described as "a sight which stamps itself ineffaceably on the memory," and that nothing in the African forest can compare with it "in charm and impressiveness," as when it flowers "this incomparable giant is transformed, as if by magic, into an enormous rose-bush of indescribable beauty, the sight of which stirs the heart of even the most matter of fact of men with admiration." This appears in a chapter on the "Primæval Forests of Central Africa," though as a matter of fact the author never seems to have entered any of the real African forests; in these, indeed, the baobab is not found, it being characteristic of the steppes and scrub-covered plains. In respect to the doleb palm, we are told on the same page that "its trunk is a pillar which no artist could have surpassed; its crown a capital worthy of such a pillar." After such a compliment, this palm cannot complain at the description of the shape of its stem being exactly contrary to the facts, it thickening at half its height from the ground instead of thinning. According to the author's account, although he tells us that Northern Africa "is desert, must be desert, and will be desert for ever," it appears to be a remarkably well-peopled desert. He says that one of the most indispensable articles in an African traveller's outfit is a pair of long-legged tongs, with which to seize the vermin that swarm into camp at night, drawn by the fire. "Attracted by the light, noxious creatures come running and creeping, first one and then another, but soon in tens and in hundreds. First appear gigantic spiders, which, with their eight legs spread out, cover a surface as large as an outstretched hand. After the spiders, or sometimes along with them, the scorpions come hurrying. Both spiders and scorpions rush with sinister rapidity to the fire, clambering over carpet and coverlet, among the dishes of our simple supper, retreating when the radiating heat becomes too strong for them, turning back again under its mesmeric influence—in truth a fearsome invasion.' After these "hellish brood" come the vipers, "unmistakably on the spot," in "terrifying numbers," which "drive one almost to despair." We fear that any one who imagines that he has only to light a fire on an African steppe to be able to fill his cases with all sorts of interesting animals, which rush to him, like rats to Bishop Hatto, would find zoological collecting less exciting and profitable than he would have expected from Brehm's description.

We have given many extracts from this work, as the best method of illustrating its nature. The book is well printed and illustrated, and the translation is very readable. Only we do not see that there is very much in it worth reading. Every page is distorted by such ludicrous exaggeration, that the descriptions run dangerously near to bathos and caricature.

OUR BOOK SHELF.

The Spas and Mineral Waters of Europe, with Notes on Balneo-Therapeutic Management in Various Diseases and Morbid Conditions. By Hermann Weber, M.D., F.R.C.P., and F. Parkes Weber, M.D., M.R.C.P. 8vo, pp. 380. (London: Smith, Elder, and Co., 1896.)

This book contains in a brief space a large amount of most useful information in regard to the spas and mineral waters of Europe. It gives the position of the various spas, their climate, baths, and mode of access, with a list of doctors and general indications of the class of cases which are benefited by the waters. Besides an enumeration of the various spas, there is a second section dealing with diseases, and mentioning the spas most likely to be useful in each. In addition to this, a full bibliography is given.

The value of the book consists, not merely in its convenient arrangement, and in the information it gives, but in the fact that most of this information is the outcome of personal knowledge on the part of the authors This gives it a precision and value which is not always

to be found in works on this subject, because the time and expense involved in visiting personally all the spas of Europe is very great, and few physicians are able to accomplish such a feat.

Domestic Science Readers. By Vincent T. Murché. Book iii. Pp. 176. (London: Macmillan and Co., 1896.)

IN the subject of domestic economy, for Standard III., the Education Department require knowledge of the chief materials used in clothing and washing, *e.g.* silk, linen, wool, cotton, fur, leather, and washing materials. This book supplies that knowledge in a form attractive to juvenile minds. The children who read the book will acquire useful information in an easy manner.

The Story of Electricity. By John Munro. Pp. 194. (London: George Newnes, Ltd., 1896.)

A SIMPLE and accurate story, containing brief but clear descriptions of the principles and applications of electrical science. The book will educate the public in the knowledge of the great achievements of electricity, and will create an interest in scientific things.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Zoological Publications.

WHEN the rules for zoological nomenclature are next under discussion, it might be advisable to include a clause relative to the discretion of editors in dealing with authors' contributions to scientific journals.

My paper (*Journal* of the Linnean Society, xxv. p. 325), before publication, was entitled "The Egg-case of Port Jackson Sharks," and it was presumed that the Port Jackson sharks, popularly so known, would be thereby understood.

As the length of time occupied by postal transit to and from London might unnecessarily delay publication, I did not ask for a proof. On receiving my copy of the *Journal*, I found that the title was altered to "On the Egg-cases of some Port Jackson Sharks;" thus the purport of the title was destroyed. Perhaps this is a small matter. One affecting me more nearly is the substitution of the name "*Cestracion*" for *Heterodontus*, which I used.

Heterodontus may be right or it may be wrong; but, as author of the paper, having adopted that name, I submit that it should have been retained. At the same time, there could be small objection to an editorial foot-note. EDGAR R. WAITE.

Australian Museum, Sydney, April 28.

THE appellation "Port Jackson Shark" is customarily applied to *Cestracion Philippi*. Macleay, as is well known, doubted the justice of including in this species the Japanese *Heterodontus zebra* (Gray); and as Mr. Waite, admitting the independence of the latter species, extends the vernacular name to *C. galeatus*, the alteration in the title of his paper is regretable, though not serious. It was made without my sanction, and I am sorry to say that it escaped my notice in the performance of my editorial duties. Had I detected it, I should not have allowed it to pass.

Concerning the substitution of *Cestracion* for *Heterodontus*, I would point out that although the latter name has priority by a year, no recent writers but Maclay and Macleay, so far as I am aware, have allowed it to stand; and that even were this not so, *Heterodontus* (1816) on the strict rules of priority in nomenclature is preoccupied by *Heterodon*, applied by Latreille to a snake in 1800.

When Mr. Waite's paper came before the Council of this Society, the matter was carefully considered, and, in accordance with instructions, I wrote him to the above effect, pointing out that I should substitute *Cestracion* for *Heterodontus* unless I heard from him to the contrary during the passage of his paper through the press. My letter was written early in July 1895, and the paper was published last February, ample time being thus allowed its author in which to reply. To this day no reply has been received. G. B. HOWES.

Linnean Society, London, June 19.

The Salaries of Science Demonstrators.

WILL you allow me to protest in your columns against what is nothing less than a public scandal, namely the advertisement by a University College, in your last issue, for a Demonstrator of Chemistry at a salary of £70 per annum?

A science demonstrator at a University College is, or should be, in some sense "a scholar and a gentleman"; and how, I ask, is a man of that type to support a decent existence on such a salary? The effect of this policy of accepting the lowest tender will be either to close such posts to those not possessed of private means—a result utterly at variance with the spirit of the time, and destructive of true efficiency—or to fill them with men of an inferior class, which would be no less harmful to the quality of our scientific education. Have we not a right to expect a more enlightened policy from the governing bodies of our University Colleges? Surely they must see that the haggling of the market does not afford the best means of fixing a teacher's reward. Even the general public cannot but recognise it to be in its own interest, that those who are chosen to educate its sons should be men of as deep knowledge and as wide culture as possible. And what width of culture and depth of knowledge can be attained on £70 a year, with the day fully occupied in the routine work of teaching, the general public itself can judge. Demonstrators of chemistry have, too, I think, peculiar cause for complaint; as a rule their duties are heavier than those of other science demonstrators, whilst their salary is the same.

In these days, even the miner has his minimum wage: cannot one be fixed for science demonstrators? It should not be less than £150, I think; certainly anything under £100 is scandalous, even in the present state of public opinion.

CHARLES FREDERIC BAKER.

Halley's Chart of Magnetic Declinations.

WITHIN the last few days I have come into possession of another early map showing Halley's lines. The date of this map is 1725, and it was published by John Senex, F.R.S. It is entitled "A Map of the World, corrected from the Observations communicated to the Royal Societys of London and Paris." The map consists of the two hemispheres, each of which is 21 inches in diameter. Around the margin in small print is Sir Isaac Newton's "Theory of the Tides," and "An attempt to Assigne the Physical Cause of the Trade Winds and Monsoons, by Dr. Ed. Halley." The map is particularly interesting, as it was evidently intended to give a full account of the winds, the directions of which in the trade winds and monsoons are indicated by arrows. Another interesting note in the margin is "Of the quantity of Vapour exhaled from the Sea, of its Circulation, and of the Cause of Springs," "Extracted from a Discourse published in the Philosoph Transact., No. 189, 192. Writ by Dr. Ed. Halley." What makes the map so interesting is the notes printed upon it referring to the magnetic declinations. The lines of magnetic variation for every 5° east and west of the line of no variation, are given in the Atlantic and Indian Oceans, but not in the Pacific.

The line of no variation is described as "The line of no variation in the year 1700." The following note is printed upon the Atlantic Ocean between the Azores and Cape Verd Isles. "These curve lines w^ch^ express y^e^ variation of y^e^ magnetical needle ware observed by D^r^ Edmond Halley for y^e^ year 1700, but it must be noted that there is a perpetual tho' slow change in the variation almost everywhere (viz.) about C. Bona Esperanza y^e^ W. variation increases about a Deg. in 9 years, in our Channel a Deg. in 7 years, on y^e^ Guinea Coast a Degree in 11 or 12 years, on y^e^ American side y^e^ W. variation alters but little: and y^e^ East variation on y^e^ S. America decreases y^e^ more Southerly y^e^ faster; y^e^ L. of no variation moving

gradually towards it." In the South of the Pacific Ocean called the Great South Sea or Mar del Zur is the following note. "The Line of no Variation y^t passes near y^e coast of China divides again y^e West from y^e East variations y^t in all probability is to be met with allmost all over this Immense Ocean; but have not attempted to describe the Curves therein wanting accounts and journals to ascertain the same." The line of no variation referred to in this note is marked on the map as passing to the west of Van Diemens Land—through New Holland and the East Indian Islands to China, and thence through China to the north of Pekin. In the Indian Ocean, just north of the Antarctic Circle, is the following note. "By the Variation of the Magnetical Needle or Mariners Compass is meant its deflection from the true Meridian, for it has been observed that there are but few places where its direction is true North but varies therefrom either to y^e Eastward or Westward in some places more in others less. Now this variation is of that great concernment in the Art of Navigation that the neglect thereof does little less than render useless one of the noblest Inventions Mankind ever yet attained to, for which reason we have here inserted them as they ware found by D^r Halley in y^e year 1700. The Curve Line passing over those places whose degrees of variation are superscribed."

The map is dedicated to the Right Honourable Richard Boyle, Earl of Burlington and Cork, &c., by John Senex, by whom it was drawn and engraved. It was "sold by J. Senex at the Globe against St. Dunstan's Church in Fleet Street, London, 1725."

THOS. WARD.

Northwich, June 13.

P.S.—I have just discovered the following note in the Indian Ocean to the South of Madagascar. "In this Indian or Eastern Ocean after you pass Madagascar y^e Westerly Variation was in y^e year 1700 on y^e decrease y^e faster y^e more Westerly and Southerly, and it was then in a manner at a stand when you came to the length of Java."

THE TOTAL ECLIPSE OF THE SUN.

THE following suggestions were compiled for a special purpose. As it is probable that many amateurs will take advantage of the coming occasion to observe the various phenomena, the suggestions are published here in the hope that they may prove useful to some who are witnessing a total eclipse for the first time.

J. NORMAN LOCKYER.

(1) *Time Observations.*

Observers who are supplied with a first-rate chronometer, of which the error and rate are known, may make valuable observations of the four contacts.

For the first contact a telescope is necessary to observe the first small encroachment of the moon on the sun's limb; of course, if a spectroscope is used to observe the gradual eclipse of the chromosphere indicated by the gradual shortening of one of the lines of hydrogen (C for choice), so much the better, but care must be taken by sweeping along the limb to secure that the chromosphere immediately above the first contact is under observation; here, of course, the line will be shortest.

The second contact will be heralded by the sweep of the moon's shadow through the air. Mr. Crommelin has calculated that in Norway this will move at the rate of two miles a second; the shadow on the land- or sea-scape will, of course, be best seen from the most elevated stations.

To observe the exact time of contact, a green shade should be used, as the disappearance of the white light of the photosphere and the appearance of the red light of the chromosphere will be emphasised. Prof. Harkness has also pointed out that the exact moment of second contact is also clearly indicated by the "seemingly miraculous appearance of the complete outline of the moon, round and black, reposing upon the wondrous radiance of the corona."

The approach of the third contact is indicated by the rapid brightening of the chromosphere at the point of the moon's limb where the sun is about to reappear. The green shade should again be used, and two or three seconds later a fine cusp of photosphere will make its appearance, announcing the termination of totality.

The green shade is here especially useful, as often the reappearance of the lower brighter chromospheric level has been mistaken for the reappearance of the sun itself.

For the fourth contact a telescope should be used if possible, otherwise a smoked glass.

It is desirable that, if possible, each party observing the contacts should consist of three persons; one to watch, without any interruption whatever, the face of the chronometer and to count the seconds immediately before each contact is expected, another to make the observation, and another to record the exact time, minute, second, and part of second at which the signal is given by the second observer.

(2) *Disc Observations.*

These observations are for noting the greatest extent of the corona, and can only be made by shore parties.

Calculate the altitude and azimuth of sun's centre, at place, at mid-eclipse. Make a disc of such a size that at a distance *from the eye* of 20, 30, or 40 feet, as may be decided on, it will cover the sun, and extend three minutes of arc beyond the limb all round.

Erect this on a vertical pole, so that from the chosen observing point it will eclipse the dark moon and the lower parts of the corona (3′ high) at mid-eclipse.

A hole should be cut in a piece of wood or cardboard, fixed at the proper height, to show the exact position of the eye. This should be free to move in altitude and azimuth to secure exact adjustment.

Test the accuracy of everything, if possible, the day before at the time the sun is nearest the mid-eclipse position.

Before totality one observer should make the adjustments before referred to, and should see that at ten seconds after the beginning of totality the lower part of the corona all round the dark moon is completely covered by the disc.

Another observer, whose eye has been lightly bandaged to make it as sensitive to faint light as possible, should then be placed at the eye-hole, and should look for the faintest extensions. He should dictate to an amanuensis the length of extensions in diameters of dark moon; and their bearing, the vertex representing magnetic north.

Immediately the totality is over, the actual observer should draw what he has seen on a card similar to that used by the sketchers of the corona (see later). This drawing should include everything seen, but the extensions should be noted with the greatest care.[1]

(3) *Eye Observations of the Corona.*

All can do serviceable work by sketching very carefully the corona during the time of totality. The observers should provide themselves with a card (or cards) one foot square, on which a circle two inches in diameter is drawn in ink, and darkened to represent the moon's disc. The diameter will serve as a scale, so that the distance the boundaries and rays of the corona extend from the dark moon may be carefully noted. Imagine both the dark moon and dark disc to represent a compass card, then the various details may be sketched at their appropriate bearings, the top of the card representing mag. N. (The points may be marked on the card in any detail that may be required, but eight should suffice.)

These observations should, if possible, be made by

[1] For phenomena thus observed in eclipse of 1878 see "Lockyer's Astronomy," p. 115.

observers in pairs, and they should not compare notes. If telescopes are used, two inches aperture and a power of twenty should be employed for choice.

Before Totality.

(I.) Note how long the corona is visible before totality, along the edge of the dark moon opposite the point at which the sun is about to disappear.

(II.) Sketch any rays visible before totality; give length, colour, and structure as well as position.

At Commencement of Totality.

(III.) Sketch general outline and rays (streamers) and rifts (dark intervals between bright rays.)

(IV.) Note if there be a blaze of light or glare where the sun has just disappeared, and whether the base of the corona is brightest near or away from prominences.

Middle of Totality.

(V.) Sketch general outline rays (streamers) and rifts; note colour and direction of greatest extension.

Near End of Totality.

(VI.) Sketch general outline, and any rays or streamers or rifts; note colours.

(VII.) Note if there be a blaze of light or glare where the sun is about to reappear.

After Totality.

(VIII.) Sketch any rays that may be visible; give length, colour, and structure, as well as position.

Questions to be answered in writing immediately Totality is over.

(*a*) Has there been any change in the appearance of the corona during the eclipse? If so, specify what change.

(*b*) Have especially the dark rays or rifts changed during the eclipse.

(*c*) Describe what has been unchanged throughout, and define its structure.

(*d*) State the colours you observed outside the red prominences.

(*e*) Were the colours anywhere arranged in layers round the sun?

(*f*) Were the colours anywhere arranged radially?

(*g*) State colours of rays, and of spaces between them.

(*h*) Did the dark rifts extend down to the moon, or did they stop short above the denser layers of the chromosphere?

(*i*) Were the rays brightest near, or far away from the moon?

(*k*) What was the comparative brightness of the rays, the bright ring near the sun, and the outer corona?

(4) *Colours of Land- and Sea-scape.*

Some time before totality there will be a notable change in the colours of sky, cloud, and land and water surfaces.

Each of these should be noted separately, and the gradual changes, both as totality is approached and after it is over, should be carefully recorded.

This apparent change of colour has its origin in the coloured chromosphere and prominences; those witnessing the eclipse are thus enveloped in coloured—generally red—light, which bathes the landscape. The sky, ordinarily blue, is seen through a red haze, and therefore puts on a purple tint.

That the sky appears more purple at some eclipses than at others, is owing to the fact that the quantity of red light is not always the same, but varies with the brightness and magnitude of the prominences visible at the time.

The following table will give an idea of the colours, both of the corona and landscape, which have been previously recorded.

Year	Inner corona	Outer corona	Rays	Landscape, &c.
1605	Reddish hue (Keple-)			
1715	Pale whiteness or rather pearl coloured (Halley)			
1733	Ruddy (Vatterini)	Greenish colour		
1766	Ruddy	Yellow and white		Livid yellow (Le Gentil).
1778	Reddish hue, pale yellow to white (Ulloa)			
1806			Bluish tint (de Witt)	
1842	Yellow			
1842	Peach colour (Airy)			Greenish olive (Pinaud) Greyish violet heavens at Lipesk.
1851	White first and then blue Dull rose colour Light violet			Land dusky yellow, water deep purple, clouds yellow, sky purple. — Dunkin.
				Sea and land dark green. Deep yellow colour beneath clouds in south. (Snow).
	Pure white Brightest (Carrington)	More feeble		Landscape dark olive tint (Hind).
	Silvery white (Swan)			Clouds deep purplish grey (Dawes)
	Light violet, nearly white (Silverstolpe) A cold unearthly light (Adams) Orange (Liveing)			A sickly neutral green coloured sea and tinged atmosphere.
1860	Yellow (Rümker)			
1869	Silvery grey (Farrell)		Fine violet mauve coloured white and yellowish white (Farrell)	
	Silvery white.	Greenish violet (Eastman)		
	Clear yellowish	Pinkish green (Myer)	Silvery	Bands of pink, purple, yellow, orange, fiery red, no green or blue except a blue tinge in purple, all divided by black stripes.

(5) *The Visibility of Stars during the Eclipse.*

The light radiated by the solar surroundings varies very much from eclipse to eclipse. Hence sometimes lamps are necessary for certain of the operations, while at others they are superfluous.

The number of stars visible, therefore, varies considerably. The sun this year at the time of the eclipse will be near the chief stars in the constellation Leo, which will be to the left of the sun.

Note, by means of a star map, what is the magnitude of the faintest stars visible, whether first, second, third, or fourth.

Suggestions for Timing the Progress of the Eclipse.

In Sicily, in 1870, the following method of recording the lapse of time during totality was introduced, and was found to prevent all excitement, and made the 80 seconds seem a long time.

Determine the number of seconds of totality at the station—say 100.

Then, at the moment of totality, let a person attached to each party of observers, carefully observing the face of a chronometer or watch, say, "You have now 100 seconds." After 5 seconds, "You have still 95

seconds." After another 5 seconds, "There are still 90 seconds remaining." And so on.

A clever man can do this in a very encouraging way. The time counter should take care not to distract himself by losing sight of the face of the watch or chronometer; and it is to be impressed upon him that much of the success of the observations will depend on his undivided attention, as his statement of time in the case of parties with large instruments, is an order to individual observers to do certain work. Hence there should be two time counters, who should change over at the middle of the eclipse, care being taken that the counting is not interrupted. *The times at which any of the phenomena occur must be noted by another observer.*

Caution with regard to the use of Telescopes.

Observers equipped with telescopes, whether they be small instruments or equatorially mounted, must be very careful about not observing the sun before or after totality without the aid of dark glasses. For small hand-telescopes a dark glass will be found sufficiently safe; but with instruments of greater power, the dark glass should be supplemented by a solar or diagonal eye-piece. If one half of the reflecting surface of the glass be silvered and the glass be made to slide, it may be used during totality. In any case, *do not forget, immediately before totality, to remove the dark glasses.*

THE KELVIN JUBILEE.

WE are glad to be able to supplement our report of the celebration of Lord Kelvin's jubilee with the address presented by M. Mascart on behalf of the Institute of France. By such cordial expressions as those in which the Institute addressed our distinguished countryman, men of science are made to feel that they belong to a universal brotherhood, all the members of which have but one aim—the accumulation of scientific knowledge. The following is the address:—

MILORD ET CHER CONFRÈRE,—L'Académie des Sciences de Paris, dans laquelle vous êtes aujourdhui le doyen des associés étrangers, a voulu se joindre aux savants de tous les pays du monde, à vos admirateurs, à vos amis, pour vous apporter des félicitations chaleureuses à l'occasion du cinquantenaire de votre arrivée comme professeur à l'Université de Glasgow que vous avez tant illustrée.

Il y a quelques mois, l'Institut de France célébrait le centième anniversaire de sa fondation, ou plutôt de la reconstitution des anciennes Académies sur des bases plus larges. Nous ne pouvons oublier l'élévation de langage avec laquelle le Président de la Société Royale de Londres vint alors traduire les sentiments de cordialité de cette grande et célèbre Institution.

Dans une autre réunion, où vous parliez en votre nom personnel, vous nous avez causé une profonde émotion en déclarant que vous aviez une dette de reconnaissance envers notre pays, que nos grand esprits tels que Fourier, Laplace et Sadi Carnot avaient été vos inspirateurs et que vous considériez la France comme l' "alma mater" de votre jeunesse scientifique.

Si la dette existe, vous l'avez payée avec usure. Dans la longue série de travaux et de découvertes qui jalonnent; votre admirable carrière, une des plus nobles que l'on puisse rêver, vous avez abordé toutes les questions des cette science a laquelle la littérature anglaise conserve le beau nom de "philosophie naturelle," soit pour contribuer aux progrès des conceptions théoriques, soit pour en déduire des applications utiles au développements de l'industrie et au bien de l'humanité.

Quoi que l'avenir réserve au génie inventif de l'esprit humain, votre nom restera comme ayant été le guide le plus sûr dans une époque féconde, et le véritable éducateur de la génération actuelle dans le domaine de l'électricité.

Je suis particulièrement heureux que l'Académie des Sciences m'ait confié le soin de vous remettre une médaille d'or à l'effigie d'Arago, médaille qu'elle réserve pour rendre hommage aux services exceptionnels rendus à la science et qui porte cette devise, "Laudes damus posteri gloriam."

Vos confrères de l'Institut de France espèrent que vous voudrez bien considérer ce souvenir comme un témoignage de haute estime et de leurs sentiments les plus affectueux.

It is due to the Council of the Royal College of Science to state that they were not less desirous than the rest of the scientific world of doing honour to Lord Kelvin. An address was prepared and signed by every member of the Council of the College, with the exception of one who was temporarily out of reach. This address was presented to Lord Kelvin at the same time as the addresses from other Colleges in London, but mention of it was inadvertently omitted from our report. A congratulatory address was also sent by the Institute of Chemistry.

THE BRITISH ASSOCIATION MEETING IN LIVERPOOL.—LOCAL ARRANGEMENTS.

THE preparations for the British Association Meeting in Liverpool next September are now going on rapidly. A large and influential Local Committee of about 500 of the leading citizens, under the chairmanship of the Lord Mayor (the Earl of Derby), was appointed a couple of years ago. The smaller Executive Committee has broken up into Sub-Committees dealing with the subjects of—(1) Finance, (2) Hospitality, (3) Buildings, (4) Excursions, (5) Publications, and (6) Evening Entertainments. Most of these Sub-Committees have been actively at work for the last few months, and a report embodying the results of their deliberations has just been submitted to a meeting of the large Committee held in the Town Hall. The following is an outline of the arrangements completed so far:—

The reception room and the general offices will be at St. George's Hall, in the centre of the town, a few yards from Lime Street Station, the London and North-Western Terminus. One of the Sections (Geography) will occupy the concert room of St. George's Hall, and three other Sections (Geology, Anthropology, and Mechanical Science) have been allotted rooms in the closely adjoining Public Museum and Walker Art Gallery. The Section of Economics will be located in the Town Hall, opening on to the Exchange flags, and in the centre of the business life of the city; while the five remaining Sections (Physics, Chemistry, Zoology, Physiology, and Botany) will be placed in the laboratories and lecture theatres of University College, about 1050 yards from the reception room. A main artery, and tramway route, leads from Lime Street to Ashton Street, from which the College opens, and arrangements will be made for a constant service of convenient omnibuses in addition to the tram-cars. Permission to use these various buildings has been obtained from the Lord Mayor and the Corporation, and the Council of University College; and the Philharmonic Hall, which holds about 3000, has been engaged for three evenings, on the occasions of the President's address and the two evening discourses. The lecture to the working classes will be given in the Picton Lecture Hall. The first conversazione will be given by the Lord Mayor (Lord Derby) in the Town Hall, and the second by the Local Committee in the range of Corporation buildings occupied by the Public

Museum and the Walker Art Gallery. The autumn exhibition will be open in September, and the Arts Committee propose to admit members of the British Association to the galleries during the week of the meeting on presentation of their tickets of membership.

A new museum, given to the zoological department of University College by the late Mr. George Holt, has been rapidly hurried on with the special view of use at this meeting, and will be available for the exhibition of specimens, models, &c., brought in illustration of papers read before the Sections, or for other objects of scientific interest sent on loan.

A number of the owners of works of manufacturing and engineering interest have offered to open their buildings for inspection during the week. Several gentlemen have intimated their intention of giving garden parties, and a number of excursions to places of interest in the neighbourhood of Liverpool have now been arranged, including the following: Half-day excursions on Saturday, September 19—(1) River excursion with the Mersey Dock Board; (2) Overhead Electric Railway; (3) Speke Hall, Hale Hall, &c.; (4) Thurstaston, Storeton Quarry (where the reptilian footprints are found), and the Leasowe Submarine Forest; (5) Bidston Observatory; (6) Chester and Hawarden; (7) Dredging excursion with the Lancashire Sea-Fisheries Steamer. Whole-day excursions on Thursday, September 24—(1) Chester and Eaton Hall; (2) Rivington Water Works, &c.; (3) Llandudno and Beaumaris by sea; (4) Manchester Ship Canal, &c.; (5) Prestatyn, Tremerchion Caves, and Corwen; (6) Northwich, Weaver Navigation, and Delamere Forest.

At the end of the meeting there will be longer excursions, extending over several days, to the Vyrnwy Water Works in Wales and to the English lakes; and a specially scientific excursion to the Isle of Man, for which a separate programme has been prepared, covering five days—Thursday to Monday inclusive.

The Earl of Derby has invited a party to Knowsley, the Duke of Westminster has also invited a party to Eaton Hall, and Mr. Gladstone will receive another party at Hawarden. In connection with the Isle of Man excursion, the Governor of the island (Lord Henniker) has invited the members to a reception at Government House, and will preside at a dinner to be given on the concluding evening.

The Publications Sub-Committee have drawn up a scientific handbook to Liverpool and the neighbourhood, containing articles on the history and antiquities, the geology, the entomology, the marine biology, the botany, the vertebrate fauna, the climate, the river and the tides, the docks and other engineering works, the trade and commerce, and the chemical industries. A complete guide to the various excursions is also in course of preparation.

The Hospitality Sub-Committee have invited as guests a large number of distinguished scientific men from the continent and America, and although many have not yet been able to give, at this early date, a decided answer, a considerable number have already definitely accepted. These include, amongst others, Prof. van Rijckevorsel (Rotterdam), M. J. Violle (Paris), Prof. V. Bjerknes (Stockholm), Prof. Lenard (Aachen), M. L. de la Rive (Geneva), Prof. Knorr (Jena), Dr. Credner (Leipzig), Prof. Renard (Gand), Prof. Mœbius (Berlin), Prof. Julin (Liège), Prof. Gilson (Louvain), Prof. Minot (Boston), Prof. Le Conte (Berkeley), Graf von Pfeil (Vienna), Prof. Cohn (Göttingen), Prof. Stainier (Gembloux), Prof. Schröter (Munich), Prof. Topinard (Paris), Dr. E. Dubois (Hague), Prof. C. Bohr (Copenhagen), Prof. Goldmann (Freiburg), Prof. Schimper (Bonn), Prof. Zacharias (Hamburg), and M. C. de Candolle (Geneva). As a number of others are still uncertain, and answers are now coming in every day, this can only be regarded as a provisional list. Probably the attendance of foreigners at this meeting will be unusually large. The Hospitality Sub-Committee is now busily engaged in arranging private hospitality for the foreign guests, and also for as many as possible of the home members of the Association who have intimated their intention of being present at the meeting.

W. A. HERDMAN.

THE DAVY-FARADAY RESEARCH LABORATORY.

SCIENTIFIC investigators have long needed a central laboratory where researches can be carried on without interruption, and have urged the establishment of a national physical laboratory for the United Kingdom. Twenty years ago the Duke of Devonshire's Commission recognised the advantages which our national industries would derive from physical and chemical investigations, and pointed out the need of a more generous recognition of such research by the State. Since then the Physikalische Reichsanstalt, at Charlottenburg, has been established, and, through the facilities it offers, Germany is reaping a rich harvest of natural knowledge; but, so far as State recognition is concerned, we have made little advancement. True, a Committee of the British Association has considered the question of a national physical laboratory, and another Committee is now reconsidering it; but there is no immediate prospect that any recommendations they might make will induce the Government to give a substantial grant, either for the extension of an existing institution in the direction of facilities for research, or for the establishment of an institution on the lines of the Reichsanstalt. For the perspicacity which sees in pure scientific research a means of developing industries, and which is content with knowledge accumulated, whether the practical bearings are apparent or not, we have to go to Germany, where many of our national industries have gone as a consequence of neglect by our Government.

Fortunately for British science, individuals occasionally arise who see how severely investigation is handicapped on account of the lack of organisation and encouragement by the State. One such benefactor is Dr. Ludwig Mond, whose munificent gift to the Royal Institution of a laboratory for physical and chemical research was warmly announced in these columns two years ago. We are now able to state that on June 12 Dr. Mond formally transferred to the managers of the Royal Institution the freehold of No. 20 Albemarle Street, adjoining that Institution, for the purpose of the laboratory of research in pure and physical chemistry referred to in our announcement, to be known as the Davy-Faraday Research Laboratory of the Royal Institution. In order to make the building suitable for this purpose, Dr. Mond has carried out very extensive alterations. He has also equipped the laboratory with the necessary apparatus, appliances, &c., for carrying on delicate investigations in physical and chemical science. An idea of the generous nature of Dr. Mond's endowment may be obtained from a statement of rooms included in the new institute.

The Laboratory contains:—

On the Basement.—A room for thermochemical research; a room for pyrochemical research; mechanics' workshop; room for electrical work; battery of twenty-six accumulators; constant temperature vaults; boiler-house and store-rooms.

On the Ground Floor.—A room for research in organic chemistry; a room for research in inorganic chemistry; a fire-proof room for experiments in sealed tubes; a balance room; entrance hall and cloak-room.

On the First Floor.—The Honorary Secretary's room; a large double library connected with the library of the Royal Institution.

On the Second Floor.—A museum of apparatus.

On the Third Floor.—Seven rooms for research in physical chemistry.

On the Fourth Floor.—A room for inorganic preparations; a room for organic preparations; a photographic room; four rooms for researches in physical chemistry.

On the Roof.—An asphalted flat with a table, gas and water.

All the floors are connected by a hydraulic passenger-lift.

Dr. Mond has not only furnished the laboratory with the most modern instruments and appliances for researches in pure and physical chemistry, but he has also placed in the hands of the managers of the Royal Institution an ample annual endowment, so that the laboratory may be maintained in a state of thorough efficiency, the object of the donor being to give every assistance and encouragement within the limits of the endowment to scientific workers.

The laboratory (the affairs of which will be managed by a Laboratory Committee appointed by the managers of the Institution) will be under the control of two directors, who will be aided in the work by competent assistants. The managers of the Royal Institution have appointed as directors Lord Rayleigh and Prof. Dewar.

It is intended to open the laboratory for work by the middle of October. The trust deed provides that no person shall be admitted to the laboratory as a worker who has not already done original scientific work, or in the alternative, who is not, in the opinion of the Laboratory Committee, fully qualified to undertake original scientific research in pure or physical chemistry; and that no person shall be excluded from admission by reason of his or her nationality or sex.

Admission to the laboratory, and the supply of gas, water and electricity, as far as available, will be free of charge; but any person using the apparatus, will be responsible for any damage done while in his possession.

Applications for admission are to be made to Mr. Robert L. Mond, Honorary Secretary to the Laboratory Committee, at 20 Albemarle Street.

The conditions of Dr. Mond's endowment are as liberal as the gift itself, and we have no doubt that the results which will follow will demonstrate the importance of both as means of advancing science. We regard the foundation of the laboratory as marking a most important step in the history of British science; for it provides a means whereby the edifice of scientific knowledge can be built up by master hands. British Governments are said to base their assistance to science mainly on the principle of helping voluntary effort. Perhaps, now that Dr. Mond has shown what can be done, the Government will show its interest in science by establishing a similar laboratory of a national character.

BORING A CORAL REEF AT FUNAFUTI.

LETTERS have just come to hand from Prof. Sollas stating that he has started from Sydney to carry out the project of putting down a boring through the atoll of Funafuti. By this time, if all has gone well, the expedition has probably started work.

It may be remembered that about six years ago, a strong committee was formed by the British Association, with Prof. Bonney as its chairman, and Prof. Sollas as secretary, "to investigate a coral reef by sounding and boring." The intention was to carry out the suggestion made by Darwin in his book on "Corals and Coral Islands," and to put to the test of fact the rival theories on the origin of these extraordinary limestone masses. After some years of preliminary thought and suggestion, a definite project began to take shape in 1894, when an application for a grant was made to the Government Grant Committee. The outcome of this was an application to the Admiralty for the service of a surveying vessel, which was most generously given for May of this year, and grants of money in aid were made by the Government Grant Committee and the Royal Society itself. A smaller executive committee of the latter body was formed, including the following names: Prof. Bonney (chairman), the President and Officers of the Royal Society, Mr. Wolfe Barry, Mr. Crookes, Mr. F. Darwin, Prof. Edgeworth David, Captain Field, Sir A. Geikie, Prof. Judd, Dr. J. Murray, Prof. Anderson Stuart, Admiral Wharton, with Prof. Sollas and Mr. W. W. Watts (secretaries), and preparations were concluded for making a start in time to leave Sydney in H.M.S. *Penguin* on May 1, under the command of Captain Field.

Meanwhile Prof. Anderson Stuart, of the University of Sydney, whose sympathy had been enlisted, entered warmly into the proposal. He took immense trouble in discussing with missionaries, sailors and travellers, the prospective merits of a large number of islands for the purpose of the investigation. Further he obtained from the Department of Mines in New South Wales the loan of a valuable set of diamond-drilling plant, and used his influence to overcome the natural difficulties which presented themselves in obtaining permission to use such apparatus on a waterless island in the Pacific. The committee is greatly indebted to this gentleman and to Mr. W. H. J. Slee, the Chief Inspector of Mines and Superintendent of Diamond Drills to the Government of New South Wales, for all the care and trouble they have taken in selecting the machinery and stores for this purpose, in engaging for the use of the expedition some of the most experienced foremen in the colony, and in obtaining a contribution towards the wages expense of the expedition.

Prof. Stuart's recommendation of the Island of Funafuti agreed with Admiral Wharton's knowledge of the island and the group to which it belongs, and it fortunately happened that further sounding and exploring of the group would furnish results of use to the Admiralty, so that a topographical and magnetic survey, together with sounding and current observations, could be carried on while the boring was being executed in the island.

Prof. Edgeworth David, from the University of Sydney, happened to be visiting England while preparations were in progress, and he furnished a most valuable means of communication with helpers in Sydney; and through this fortunate circumstance, the committee was able to come into closer touch with the Sydney committee in order to provide more completely for the regular work and such emergencies as could be foreseen. It was hoped that either Prof. David, or Mr. Pitman, the Government Geologist of New South Wales, would be able to take part in the expedition, but unfortunately neither gentleman could arrange to be away at the time requisite. Mr. Hedley, from the Australian Museum, has, however, been able to go, and he will utilise his opportunities for collecting and making observations in natural history.

Prof. Sollas, who is sent out by the committee in chief charge, will regard the boring work as the principal aim of the expedition, and will only be able to utilise his spare time in any other work. All of his observations, however, he intends to devote to the primary object of elucidating the structure and origin of the reef. It is therefore a good thing that Mr. Stanley Gardner, an enthusiastic Cambridge naturalist, has been able to accompany him, and he purposes to devote himself to biological work of such a nature as to bear directly on the origin and growth of reefs.

Funafuti is a typical atoll, submerged for the most part on its western side, but above water for a long strip on its eastern side. It is about fifteen miles in circumference and about seven miles in longest diameter, is one of a group of atolls situated due north of the Fiji group, and is about in latitude 10° S., and longitude 179° E. The

lagoon has a good entrance, and provides firm anchorage. There are about 400 inhabitants, with a native missionary and a white trader; but there is no good supply of water on the island.

Apparatus is being taken for boring about 1000 feet, but it is not anticipated that the bore will reach more than 700 feet in the time allotted, although three shifts will be working night and day, but not on Sundays, for the inhabitants are strict Sabbatarians. Delays are almost certain to occur, for the rock will be in places soft and cavernous, and the occasional dropping of the crown, resulting in probable injury to the diamonds, is not unlikely. For this reason the Department of Mines in New South Wales has provided steel cutters, which will be used whenever the nature of the rock permits it. The hole will start at four inches diameter, and it may be necessary in the later stages to drop to three inches, for which apparatus will be at hand.

The necessity for an investigation into the submarine structure of a coral reef is so well known to the readers of NATURE, that it is unnecessary to enter into any minute particulars. The explorers are instructed to bring back a core which will show what the under parts of a typical atoll are made of, and thus make known, what there has never been an opportunity of studying before, the foundations and under-structure of a reef which has not received sufficient uplift to clear the water. The different parts of this core will almost certainly indicate how its component rocks have originated—by living coral growing on coral *in situ*, on coral débris, on other types of organic rocks, or on a platform of denudation or deposition.

"Of the cores and of such other specimens as may be collected by the expedition (not referring to specimens collected by the volunteers in their private capacity), the first set will be ultimately presented to the British Museum, the second to the Ministry of Mines at Sydney."

In conclusion, I may be allowed to point out that though a large sum of money has been granted by the Government Grant Committee and by the Royal Society, it would have required very much more if the Admiralty had not made a most speedy and generous response to the request of the Royal Society. Even with that help, it would have been impossible to do the work so soon, or even probably at all, if further ready and kindly assistance had not been received from individuals mentioned above, and from the Department of Mines of the Government of New South Wales. The help thus rendered has probably reduced by three-fourths the total cost of the exploration, and it will be readily understood that the English committee feels a lively gratitude, not only to the Admiralty and its advisers, but to our good friends in New South Wales, amongst whom it is a pleasure to name Prof. Anderson Stuart, Mr. Slee, and Prof. Edgeworth David, not forgetting Sir Saul Samuel, the Agent-General of the Colony in England.

W. W. WATTS.

SIR JOSEPH PRESTWICH, D.C.L., F.R.S.

THE most eminent of British geologists has just passed away, and those who last Saturday stood around his grave amid the chalk hills of his pleasant country home at Shoreham, near Sevenoaks, felt that they were paying a last tribute to a veteran who had outlived all the associates of his prime, who had completed all his earthly tasks, and had gone to rest full of honours, and revered by all who knew him.

Joseph Prestwich was born in 1812 at Clapham, and after passing through elementary schools in London and in Paris, he proceeded to the famous grammar school of Dr. Valpy at Reading, and completed his education at University College in Gower Street. At this college his thoughts were directed to science by the lectures of Edward Turner on chemistry, and of Dionysius Lardner on natural philosophy. Turner, moreover, introduced the subjects of geology and mineralogy into his course, and thereby Prestwich gained those first lessons which aroused his interest and led him by force of circumstances to devote his leisure to geological studies. Had he been free to take up a profession he might, indeed, have given his special attention to chemistry. He was, however, destined to enter into commercial life, and until he was sixty years of age he was busily engaged in the city as a wine merchant. Assiduous and successful as a man of business, he yet contrived, from his earliest years in the office, to give great attention to geology, and he devoted all the leisure he could command to this subject, first of all as a means of relaxation, and finally because his interests were centred in the study. In early years his business-journeys enabled him to see and learn much about the general geology of England and Scotland; and when still a youth he spent his holidays during two successive years in studying the district of Coalbrook Dale in Shropshire, in mapping the various strata exposed at the surface from the Silurian rocks to the New Red Sandstone and Drifts, in marking the lines of fault, in noting in detail the character of the Coal-measures, and in gathering together the fossils from the several formations. The masterly memoir which he wrote on this area was communicated to the Geological Society of London in two portions in 1834 and 1836, being completed when the author was but twenty-four years of age. Meanwhile he had paid a visit to the north of Scotland, and had given some account of the Ichthyolites of Gamrie in Banffshire, a task which he undertook at the suggestion of Sir Roderick (then Mr.) Murchison. This was his first paper published in the *Transactions* of the Geological Society, of which he had been elected a Fellow in 1833.

Later on he came to devote his special attention to the Eocene formations in the neighbourhood of London, and in course of time he thoroughly investigated the entire area of the London Basin. In particular he defined and named the Thanet Sands and the Woolwich and Reading Beds; and he studied the sequence of organic remains in the London clay, and the subdivisions of the Bagshot series. In these researches he paid especial attention to the lithological changes of the strata and to their fossils, so that he could picture the physical conditions under which the several formations were deposited. He extended his observations into the Hampshire Basin, and showed that the Bognor beds formed part of the London clay, and eventually he proceeded into France and Belgium to correlate the subdivisions there made with those he had established in this country. This great work among the Eocene strata occupied much of his time for nearly twenty years, and it served to fully establish his reputation not only as a keen and accurate observer, but as a most philosophical geologist. Another great achievement soon awaited Prestwich, and that was the investigation of the valley gravels supposed to contain the works of man in association with extinct mammalia. Boucher de Perthes had in 1847 announced such discoveries in the Somme Valley, but they had received little attention. The somewhat similar discoveries in Kent's Cavern, by MacEnery, had likewise been neglected. Attention was, however, forcibly directed to the subject by the discoveries made in Brixham Cave in 1858, and Dr. Falconer then induced Prestwich to examine the evidence brought forward in the valley of the Somme. The results of these researches, which were carried on in conjunction with Sir John Evans, and which were followed by a study of the English evidence at Hoxne, in Suffolk, in the Ouse Valley, and elsewhere, are well known. The contemporaneity of man with the Mammoth and other Pleistocene mammalia was fully established,

and the antiquity of man came to be the most absorbing topic of the day. That vexed question still remains a matter under discussion, although Prestwich, in some of his later articles, has sought rather to reduce than to extend the time-limits of man's existence.

Subjects of practical importance from time to time engaged his attention. In 1851 he published "A Geological Inquiry respecting the Water-Bearing Strata of the country around London," a work which at once became the standard authority on the subject, and has lately been reissued with appendices. The author took a prominent part on the Royal Commission on Metropolitan Water Supply in 1867, and his services were again in request on the Royal Coal Commission, to the reports of which, published in 1871, he contributed accounts of the Bristol and Somerset Coal-field, and of the probable extent of Coal-measures beneath the Secondary rocks of the south and south-east of England. Agreeing generally with the conclusions of his friend Godwin-Austen, he was led to infer that concealed coal-fields might extend from Somersetshire eastwards to the neighbourhood of Folkestone. Subsequent explorations at Dover have shown the correctness of these theoretical views.

Prestwich was elected a Fellow of the Royal Society in 1853, and was appointed a Vice-President in 1870. In that same year he was chosen President of the Geological Society, and in the course of his two addresses he dealt with the subjects of deep-sea researches, and water-supply.

His attention had been given at various intervals to the later Tertiary deposits, and in 1871 his three great papers on the structure of the Crag-beds of Suffolk and Norfolk were published by the Geological Society. So much had been written by others on these very fossiliferous strata, that the author had not scope for so much originality as was the case with his Eocene researches. These later papers were, however, characterised by the same exhaustive treatment of the subject, in the record of many sections, and in the enumeration of the organic remains. His memoirs on the Pliocene or Crag formations were eventually followed by a series of articles dealing with more recent deposits. In the meanwhile Prestwich, who had retired from business in 1872, was offered the chair of Geology at Oxford, vacant through the death in 1874 of John Phillips. It came rather as a surprise to his friends that a man who had achieved such distinction and had earned repose should again go into harness. A young and ardent teacher would, however, at that time have been out-of-place, and, as events proved, no one better than Prestwich could have been selected to fill the post with such advantage to the University.

One result of his labours in Oxford was his large and handsomely illustrated work, in two volumes, entitled "Geology Chemical, Physical, and Stratigraphical"—a work in which he opposed the strictly uniformitarian teachings of some geologists, and urged that, though the agents were similar in kind in past ages, they were not similar in degree to those of the present day. Retiring from Oxford in 1888, Prestwich again surprised his many friends by his renewed activity. Paper after paper issued from his pen, dealing with the most difficult problems connected with the later superficial deposits—notably his memoir read before the Royal Society on the "Evidences of a Submergence of Western Europe and of the Mediterranean Coasts at the close of the Glacial or so-called Post-Glacial Period." He dealt also with the rudely-made plateau flint-implements of the Chalk Downs, many of them found near his Kentish home. Although individually they would not attract much notice, he maintained that these rudely-chipped flints bore traces of human workmanship, and collectively showed evidence of a peculiar type of earlier date than the ordinary Palæolithic implements.

These later writings of Prestwich have initiated many new lines of inquiry, even if they have failed to carry conviction to all his readers.

The last honour bestowed upon him, in the early part of this year, was that of knighthood, which he was unable to accept in person from Her Majesty owing to his feeble health. He died on June 23, at his home, Darent Hulme, near Shoreham. H. B. W.

NOTES.

The Albert Medal of the Society of Arts has been awarded, with the approval of H.R.H. the Prince of Wales, the President of the Society, to Prof. David Edward Hughes, F.R.S., "in recognition of the services he has rendered to arts, manufactures, and commerce by his numerous inventions in electricity and magnetism, especially the printing telegraph and the microphone."

The Swiss Society of Electrical Engineers is organising an International Electrical Congress, which is to take place at Geneva from August 4 to August 9 next, under the presidency of M. Turrettini. The following subjects are to be discussed at the Congress: (1) Magnetic Units, (2) Photometric Units, (3) Transmission and Distribution of Power to Great Distances by means of (*a*) Direct Currents, (*b*) Alternate Currents, (4) Protection of High-pressure Overhead Electric Lines against Atmospheric Discharges, (5) Various Disturbances caused by Electric Traction. Further information can be obtained from the Bureau du Congrès International des Électriciens, Université, Genève.

It has been proposed that some token of esteem be presented to Prof. N. Story-Maskelyne in recognition of his distinguished services to mineralogical science, and to commemorate his long connection with the University of Oxford. The presentation is intended to take the form, if possible, of a portrait, and it is believed that contributions not exceeding £2 in amount will be sufficient for the purpose. A number of men of science, both at home and on the continent, have already promised their support. Contributions will be received by Prof. A. H. Green, F.R.S., or Prof. H. A. Miers, F.R.S., University Museum, Oxford.

The Board of Managers of the New York Botanical Garden have issued the first number of a *Bulletin*, containing the Act of Incorporation, and a map of the site for the Garden granted by the Commissioners of Public Parks. By agreement with the Trustees of Columbia College, the botanical library and herbarium belonging to that institution will be deposited in the Botanical Garden. The endowment fund of 250,000 dols. required by the Act of Incorporation has now been fully subscribed. The President of the Board of Managers is Mr. Cornelius Vanderbilt; the Secretary, Prof. N. L. Britton.

Mr. Austin Corbin, who was killed a few days ago in New Hampshire, had acquired a herd of fifty buffalo, which he kept in his preserves in that State. It was his intention to lend the animals for an indefinite period to the city of New York, and a plot of eighty acres in Van Cortlandt Park, in the northern (annexed) portion of the city, had been prepared for them, having been surrounded by a fence seven feet high. The plan will be carried out by his representatives, and the herd will be moved in the autumn; the delay being caused by apprehension that change of climate during hot weather might prove pernicious. This measure may avert the threatened extinction of the buffalo, which has now been almost extirpated on the western plains.

Mr. J. H. T. Tudsbery has been appointed Secretary of the Institution of Civil Engineers, in succession to Mr. James Forrest, who has retired.

A REUTER telegram from St. Petersburg says:—"Despatches from Irkutsk announce that M. Hansen, the Norwegian trader, left that town on June 1 for the north of Siberia. His journey is primarily for trading purposes, but he will also inquire into the truth of the recent rumours regarding Dr. Nansen, and see if the store of provisions left by Baron Toll in the New Siberian Islands for Dr. Nansen is still intact. M. Hansen's mission has been confided to him by the Russian Imperial Geographical Society."

THE cruellest deed committed for the gratification of feminine vanity is the destruction of small white herons or egrets, during the season in which they have their nests and young, in order to supply plumes for ladies' hats. By persistent appeals the Society for the Protection of Birds have induced a small proportion of the gentler sex to give a thought to the conditions under which their borrowed plumes are obtained, and a slight feeling against the fashion of wearing feathers has been aroused. But fine feathers are so essential to feminine decoration, that the slightest excuse is sufficient to salve the conscience. Happy were the ladies, therefore, when they were told by shopkeepers that lovely delicate plumes for the decoration of hats were now artificially made, and no peculiar cruelty was necessary to obtain them. But their complaisance has been disturbed. Sir William Flower has examined numbers of plumes, the wearers of which were priding themselves on their humanity, trusting to the assurance of the milliner that they were not real egret's feathers, but manufactured, and he has found in every case that they were unquestionably genuine. The only "manufacture" consisted in cutting the plume in two, and fixing the upper and lower half side by side, so that a single feather does duty for two in the "brush." Simply to keep up their trade and dispose of their stock, the purveyors of female raiment have invented and widely propagated a monstrous fiction, and are everywhere selling the real feathers warranted as artificial! "Thus," concludes Sir William Flower, "one of the most beautiful of birds is being swept off the face of the earth, under circumstances of peculiar cruelty, to minister to a passing fashion, bolstered up by a glaring falsehood."

IN order to determine the highest possible speed that may be attained on railways, trial runs were lately made between Berlin and Lübbenau on the Berlin and Görlitz line, states the *Engineer*; and for these runs a special express engine of new design with four cylinders and driving wheels of 2 metres (6ft. 6in.) diameter has been constructed, thus giving the engine a much greater height above the rails than usual. The composition of the trains was very various, amounting sometimes to 100 axles. With a train of 30 axles the highest performance, viz. 106 kiloms. ($65\frac{3}{4}$ miles) per hour was recorded, being 20 kiloms. (12 miles) more than the highest speed hitherto attained by the quickest German lightning train (Blitzzüge), viz. the Berlin Hamburg D-Zug, which runs through a distance of 286 kiloms. ($177\frac{1}{2}$ miles) in $3\frac{1}{2}$ hours, while the speed of ordinary German expresses is only 70 kiloms. ($43\frac{1}{2}$ miles) per hour. The portions of lines chosen for the runs were tolerably horizontal over their whole length, and had very few curves.

OUTBREAKS of anthrax are by no means easy to trace to their fountain-head; and the Canton of Zürich has recently been much exercised over the appearance of anthrax in a district where this disease had previously been unknown. Dr. Silberschmidt, one of the assistants of the Hygienic Institute attached to the University of Zürich, has been entrusted with the task of ferreting out, if possible, the means by which anthrax has been introduced. Suspicion had fallen upon a horse-hair factory in the vicinity of the infected area, where the raw material employed emanated principally from Russia, from which country it is imported direct *viâ* Leipzig, in large bundles weighing over a hundredweight. These bundles are subjected to no process whatever of sterilisation or cleansing; and as cases of anthrax, whilst rarely met with amongst horses in Switzerland and other European countries, are comparatively frequent in Russia, the suspicion of this factory being the probable source of the trouble seemed justified. Careful examinations of some of this horse-hair, and also of the dust in the factory, revealed the undoubted presence of anthrax germs; thus the dissemination of anthrax appeared to be readily accounted for, and its distribution in the spore form as dust, in consequence of the extraordinary vitality of anthrax spores, renders it a particularly dangerous foe to deal with. It has been suggested to the authorities that Russian horse-hair should be sterilised on the frontier, or at any rate in Leipzig, in special apparatus arranged for the purpose, as, after the raw material has been distributed to small factories, the expense of sterilisation renders its being successfully carried a matter of great difficulty.

THE vexed question in the theory of fluid friction, whether finite slipping does or does not take place at the surface of a solid in contact with a liquid, forms the subject of a contribution, by Dr. Antonio Umani, in a recent number of the *Nuovo Cimento*. The experiments were conducted in the physical laboratory of the University of Parma, the apparatus used consisting of a cylindrical box filled with mercury, and suspended by a torsion fibre. In one series of experiments the sides of the box were nickel-plated, so that the mercury did not actually wet the metal; in another series, the mercury was made to bathe the sides of the box by thoroughly amalgamating the latter. In the former case, the presence of a film of air between the mercury and nickel was obviated by filling the box *in vacuo*. The observed values for the logarithmic decrement of the amplitude of the oscillations were found to differ in the two series of experiments by an amount which, Dr. Umani considers, indicates finite slipping between the mercury and the box when the latter is nickel-plated. The author further proceeds to calculate the internal coefficient of viscosity of mercury from the results of his second series of experiments, and obtains the value $\eta = 0{\cdot}01577$ C.G.S. units at temperature 10° C. Warburg, employing Poiseuille's method, had previously obtained at temperature 17°·2 C. the value 0·01602.

IN the *Bulletin* of the Royal Academy of Belgium, M. Léon Gerard contributes the results of some observations on the seat of emission of Röntgen rays, and their mode of propagation in air. The rays emanating from a Crookes' tube were allowed to pass through three diaphragms, and the emergent pencil of light was received on a photographic plate placed in different positions, so as to give both transverse and oblique sections of the pencil. By comparing these various sections, M. Gérard has been led to the conclusion that Röntgen's statement, according to which air is much less absorbent to Röntgen rays than to kathodic rays, is inexact. He considers that both kinds of rays possess the analogy of not travelling exactly in straight lines, and that, in accordance with the views of Lénard, atmospheric air is a turbulent medium for kathodic manifestations, and that their transmission takes place as in a turbulent medium, such as stearin or milk. M. Gérard's second conclusion, namely, that Röntgen rays only emanate from the surface of the glass on which kathodic rays fall, is in accordance with the numerous investigations described in previous numbers of NATURE.

THE action of Röntgen and other rays on the higher animals has been studied by Prof. Stefano Capranica (*Atti R. Accad. dei Lincei*). The subject selected for observation was *Mus musculus*, and the experiments referred chiefly to the quantity of carbon dioxide exhaled in the process of respiration. Prof. Capranica states the following conclusions: (1) The amount of CO_2 is the same in darkness as in diffuse daylight. (2) The

respiration of *Mus musculus* is greatly affected by strong sunlight, even when all heat-rays have been screened off; and the effect is the same for rays from all parts of the spectrum. (3) Artificial lights, such as the electric light or incandescent gas, act like sunshine when concentrated on the animals, but have no effect when merely used to light a room. (4) The light from Geissler's tubes has no effect. (5) Röntgen rays have no action on the quantity of CO_2 eliminated from the animal, whatever be the conditionof the latter; that is, whether fasting or after feeding, whether previously kept for several hours in darkness, or *vice versâ*. (6) What was observed with each of the six moles experimented on was strong excitement, which continued for several hours after the experiments with Röntgen rays had ceased. The moles, after being exposed to Röntgen rays for one hour, ran about in a nervous and excited way, and would not eat. (7) This excitement Prof. Capranica attributes to the electrical effects of the Röntgen rays. (8) Experiments on cold-blooded animals (*Coronella*) give, as yet, no appreciable results.

THE meteorological and astronomical work accomplished during 1895 in the Observatory of the Mersey Docks and Harbour Board, are stated by Mr. W. E. Plummer in a report just received. Appended to the general tables is a catalogue and short discussion of all the gales of wind that have been automatically recorded with velocities equal to, or exceeding, fifty miles per hour. Several interesting points are brought out by the catalogue. It appears that the average length of a storm at Liverpool, as defined by the condition that the wind velocity shall exceed fifty miles per hour, is about six hours; while the average number of stormy hours in a year does not greatly exceed sixty. With regard to the time of year in which these disturbances occur, general experience points to a connection between them and the observed temperature. This agreement is very clearly shown by Mr. Plummer in a diagram having a curve exhibiting the number of stormy hours in each month, and an inverted temperature curve. The two curves very markedly coincide with one another. By means of two other diagrams Mr. Plummer shows the connection between barometric height and wind velocity; the variation of the barometer being taken from the time when no indications of a gale were apparent to the time when the disturbance ceased. There is a distinct difference between these variations and the wind velocity in the cases of winter and summer storms. In the winter, the fall of the barometer coincides with some approximation to the increase in the severity of the storm, but on the average the time of minimum barometer precedes the time of maximum velocity by about four hours. The mean length of time from the beginning to the end of the storm is twenty-six hours, of which twelve are occupied in the increase, and fourteen in the decrease of violence. The rise in the barometer after the time of maximum velocity is more marked than in the fall, and the mercury stands considerably higher at the end than at the beginning In the summer, the average length of time embracing the whole of the disturbance is reduced to twenty-two hours. The fall of the barometer as the storm gathers force is very slight, and on the average only amounts to 0·04 inch, while the minimum barometer occurs five hours before the maximum wind velocity. In nearly half the storms examined the barometer rose steadily throughout the whole of the disturbance. Mr. Plummer could find no instance of a storm occurring in the summer months when the barometer stood above 30 inches: in winter, 10 per cent. of the storms were developed at that pressure.

THE seventh volume of the *Geographical Journal* (new series), containing the monthly numbers from January to June of this year, has been published with commendable promptitude. The volume is a wonderfully interesting record of travel and discovery, and, with its notes, descriptive lists of geographical literature, new maps, and illustrations, it is an invaluable publication to geographers.

A SERIES of sixteen reproductions of photographs obtained by means of Röntgen rays, together with text (in Japanese) explanatory of the methods by which they were obtained, has been received from Prof. Y. Yamaguchi and T. Mizuno, of Tōkiō University. The photographs are much less distinct than those obtained since the introduction of the focus tube, but they nevertheless show that Japan means to keep in the van of scientific progress.

A CONTRIBUTION to the theory of warning colours and mimicry appears in the *Journal* of the Asiatic Society of Bengal (vol. lxv. Part ii. No. 1, 1896). Mr. Frank Finn, Deputy Superintendent of the Indian Museum, has tested the taste of the common garden lizard of India (*Calotes versicolor*) for various insects, and especially for butterflies protectively coloured and plain. Mr. Finn thinks the behaviour of the reptiles at liberty does not afford support to the belief that the butterflies, at any rate, usually considered nauseous, are distasteful to them.

WE understand that the next instalment of the "System of Medicine," which Prof. Clifford Allbutt is editing for Messrs. Macmillan and Co., will deal with Gynæcology, and will appear in the course of September. Dr. Playfair is associated with Prof. Allbutt as editor of this volume, which, though uniform with the system, will be complete in itself. The second volume of the "System of Medicine" proper may be expected by the end of the year. Messrs. Macmillan and Co. will also shortly issue a work on "Deformities," by Mr. A. H. Tubby. It is a comprehensive treatise on orthopædic surgery, and is fully illustrated by two hundred original plates and figures, and notes of one hundred cases.

THE June number of the *Journal* of the Chemical Society is an exceptionally bulky one; it runs into nearly four hundred pages, seventy-five of which are taken up with abstracts of papers. A distinguishing feature of the number are the four detailed accounts contained in it of Hofmann and his work. These are:—"Personal Reminiscences of Hofmann and of the conditions which led to the establishment of the Royal College of Chemistry and his appointment as its Professor," by Lord Playfair; "The History of the Royal College of Chemistry and Reminiscences of Hofmann's Professorship," by Sir F. A. Abel; "The Origin of the Coal-Tar Colour Industry, and the Contributions of Hofmann and his Pupils," by Dr. W. H. Perkin; and "Notes on Hofmann's Scientific Work," by Dr. H. E. Armstrong. Students of chemistry will find these descriptions full of interesting personal reminiscences, and will derive from them an idea of the marvellous amount of work which Hofmann accomplished.

THE Lepidoptera collected in Eastern Africa by Dr. W. L. Abbott have been determined by Dr W. J. Holland, and a list of them, with some other collections, is given in an excerpt from the *Proceedings* of the U.S. National Museum (vol. xviii pp. 229-279). The collection from Eastern Africa was found by Dr Holland to contain only a small number of species new to science, the great majority being species well known from other localities, and noticeably from temperate South Africa, many of them species named in the last century. It is pointed out that the presence of an *Argynnis* and a *Chrysophanus* in the collection is peculiarly interesting, and suggests to the student the thought that when a more thorough exploration of the lofty heights of Kilimanjaro, Kenia and Ruwenzori shall have been made, there will be some very remarkable, if not astonishing, facts brought to light as to the geographical distribution of animals. A collection made by Dr. Abbott in the islands lying west and north of Madagascar in the Indian Ocean, also possesses interest as illustrating the geographical distribution of genera

and species. Dr. Holland finds it to be made up of certain genera possessing great capabilities for migration, and apparently a strong power to resist change under varying conditions. The other collections of Lepidoptera described by Dr. Holland in the excerpt referred to, were obtained from Somaliland, by Mr. W. A. Chanler and Lieut. von Hoehnel; and from Kashmir, by Dr. Abbott.

The Connecticut Agricultural Experiment Station was established in 1877 "for the purpose of promoting agriculture by scientific investigation and experiment." The nineteenth annual report, containing an account of the work carried on during 1895, shows that both the science and practice of agriculture are advanced by the researches at the Station. The papers on the agricultural value of fertilisers and the availability of nitrogen alone furnish the materials for a liberal education in agriculture. Hundreds of analyses have been made in the chemical laboratory, while diastase—the sugar-forming ferment of sprouting seeds—and the proteids of the potato, malt, pea, vetch, and other plants have been studied, and new results obtained with reference to them. Experiments on the efficacy of the corrosive sublimate treatment of potato seed, where the land which is planted with potatoes is already fully infested with the potato-scab fungus, showed that the treatment was of little avail in preventing scab upon the crop. It was found that the addition of lime in quantities to the soil of the experimental field increased the amount of scab. The dreaded San José scab appeared in Connecticut for the first time in 1895, and great credit is due to the State Experiment Station for the prompt and thorough manner in which they gave nurserymen information regarding the occurrence, characteristics, and life-history of the insect, and the methods which have proved successful in eradicating it. Many other matters occupied the attention of the staff of the Station during the year covered by the report, and the results have been made known to the farmers of Connecticut. All the work proper to the Station that can be used for the public benefit is done without charge. Further, we read: "Every Connecticut citizen who is concerned in agriculture, whether farmer, manufacturer, or dealer, has the right to apply to the Station for any assistance that comes within its province to render, and the Station will respond to all applications as far as lies in its power." This announcement is sufficient guarantee that the Station is never in want of subjects for investigation, and the *Bulletins* and Reports published from time to time testify to the great value of the work undertaken and results obtained.

The additions to the Zoological Society's Gardens during the past week include three Indian Stock Doves (*Columba eversmanni*), a —— Duck (*Nyroca baeri*), three —— Hemipodes (*Turnix dussumieri*) from India, presented by Mr. Frank Finn; a Peba Armadillo (*Tatusia peba*) from South America, eight Bell's Cinixys (*Cinixys belliana*) from Angola, a Maximilian's Terrapin (*Hydromedusa maximiliana*) from Brazil, a Madagascar Boa (*Pelophilus madagascariensis*), a Madagascar Tree Boa (*Corallus madagascariensis*) from Madagascar, deposited; two Plantain Squirrels (*Sciurus plantani*) from Java, an Occipital Vulture (*Vultur occipitalis*) from Africa, two Burmeister's Cariamas (*Chunga burmeisteri*) from the Argentine Republic, two Crowned Partridges (*Rollulus cristatus*) from Malacca, twelve Spotted Tinamous (*Nothura maculosa*) from Buenos Ayres, two Chilian Teal (*Querquedula creccoides*) from Antarctic America, two Shamas (*Cittacincla macrura*), a Malabar Green Bulbul (*Phyllornis aurifrons*) from India, a —— Sand Snake (*Psammophis schokari*), a Hissing Sand Snake (*Psammophis sibilans*) from Egypt, purchased; a Brush-tailed Kangaroo (*Petrogale penicillata*), two Spotted Pigeons (*Columba maculosa*), two Triangular-spotted Pigeons (*Columba guinea*), two Vinaceous Turtle Doves (*Turtur vinaceus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

Declinations of Fifty-six Stars.—The definitive declinations and proper motions of fifty-six stars have been determined at the Columbia College Observatory (*Contributions*, No. 8). The stars in question were selected by Profs. Fergola and Jacoby for observation at Naples and New York by the Talcott method, for the determination of the variation of latitude, and for the calculation of the constant of aberration by Küstner's method. Prof. Jacoby commenced the investigation, but ill-health compelled him to relinquish it, and it was continued by Mr. Davis. The discussion of the declinations was undertaken with the object of obtaining results based upon all available observations, so as to make this part of the work of value as an independent research. The memoir involves observations recorded in no less than 130 star catalogues, and represents an enormous amount of painstaking computation.

Graphical Prediction of Occultations.—The usual methods of deriving the local circumstances of an occultation, either graphically or by calculation, are somewhat lengthy and tedious, but a new construction, described by Major Grant, R.E., in the June number of the *Geographical Journal*, is rapid, simple, and sufficiently accurate for most purposes. With the aid of a convenient diagram the parallaxes in declination and right ascension of any heavenly body are readily determined, and when applied to the moon the elements of an occultation are easily deduced. It is stated that after a little practice the whole process can be performed in about twenty minutes, and that, with moderate care, the error of the time of disappearance or reappearance should not exceed ten minutes, while the angles of ingress and egress need not differ more than one or two degrees from those calculated. Separate copies of the paper, with the diagrams suitably mounted, can be obtained on application to the Royal Geographical Society.

Mass of the Asteroids.—In a paper under the title of this note (*Ast. Nach.*, No. 3359), G. Ravené attempts to determine the most probable mean value of the total mass of the minor planets, on the basis of the secular perturbations of the perihelion point of Mars. The best result given in Newcomb's recent work on the subject (*Bull. Ast.*, xiii., January 1896), shows that the perihelion motion of Mars is not entirely that given by theory, unless an empirical amount of about $5''.55$ in a century be taken into consideration. It is obvious that at least part of these perturbations may be attributed to the disturbing force of the minor planets, and this is rendered more probable when Barnard's recent measures of the diameters of the four chief asteroids are taken into account. From these it was concluded that the asteroids are by no means so small as the previous photometric measurements had indicated, and it is not certain that such data are useful for a precise estimate of the mass of these small bodies.

An asteroid like Ceres, having a diameter of about 485 miles, will have a mass of about 1/4000th part of the earth's mass, if we assume it to have an equal density. It is thus quite likely that in a considerable length of time the total mass of all the asteroids will be sufficient to cause appreciable perturbations of the elements of a neighbouring planet.

In considering the theory of this action, it is assumed that the asteroids are distributed in an elliptical ring round the sun, and by noting the excess of perturbation produced on neighbouring bodies, using Gauss's method for calculating secular perturbations, the mean mass of the ring is found to be $= 1/37,130,000$ the sun's mass, or $= 1/115$ the earth's mass.

Variable Stars.—Harvard College Observatory *Circular*, No. 7, gives particulars of the discovery of seven new variables, and also of the confirmation of variability in three stars previously suspected by other observers. Three of the variables have spectra of the *third* type, showing also bright hydrogen lines. Three others have spectra of the *fourth* type. The star $-33°$ 14076 was found to be variable by Colonel E. E. Markwick, of Gibraltar, but no photographic confirmation was obtained until Mrs. Fleming ascertained that a star having a peculiar spectrum was identical with this. Detailed examination of all the plates of this region, eighty-nine in number, then showed it to vary in magnitude from 11·3 to 6·4. The spectrum of the star has bright lines which show evidence of change.

A large number of observations has been made with the meridian photometer to determine the forms of the light

curves of variable stars of the Algol type. S. Antliæ has usually been regarded as belonging to this class, and is specially interesting on account of its short period of 7h. 46·8m., and because it is said to retain its full brightness for *less* than half its period, this last peculiarity being opposed to the probability of the variation being due to a dark eclipsing body. On constructing a curve from a series of 177 measures, the conclusion is that S. Antliæ is not a star of the Algol type, but its light is *constantly* changing, and that it should rather be classed among the variables of the δ Cephei or η Aquilæ type. An interesting feature of the light curve for this star is that the increase of light is slower than the diminution. As this ratio (0·62) in most other short-period variables is from 0·20 to 0·33, there seems reason for dividing the two classes.

The star β Lyræ is commonly regarded as a variable of short period of the same class as the above. "Observations of its spectrum, however, show that two or more bodies, revolving round each other, are present. The light curve found by Argelander may be closely represented by assuming that the primary minimum is caused by the eclipse of the brighter body by the fainter, and the secondary minimum by a similar eclipse of the fainter body by the brighter. This star should therefore be taken from the class of ordinary short-period variables and included among the stars of the Algol type." Lockyer finds, however, that there is evidence of greater complication in the system; and the theory of eclipses alone fails to account satisfactorily for the velocities in the line of sight which are obtained from the measurements of photographs of the spectrum of the star.

AWARD AND PRESENTATION OF THE RUMFORD PREMIUM.

IN conformity with the terms of the gift of Benjamin, Count Rumford, granting a certain fund to the American Academy of Arts and Sciences, the Academy is empowered to make, at any annual meeting, an award of a gold and silver medal, being together of the intrinsic value of three hundred dollars, as a premium to the author of any important discovery or useful improvement in light or in heat, which shall have been made and published by printing, or in any way made known to the public in any part of the continent of America, or any of the American islands; preference being always given to such discoveries as shall, in the opinion of the Academy, tend most to promote the good of mankind.

At the annual meeting of 1885, the Academy awarded the Rumford premium to Thomas Alva Edison for his investigations in electric lighting, and the presentation of the medals took place at the meeting of May 13, 1896.

Vice-President Goodale, in presenting the medals, made the following remarks:—

"It would be highly presumptuous for one whose knowledge of physics is of the most elementary character to occupy the time of the Academy by any statement of his own in conveying these medals. Happily such a course is unnecessary. The Chairman of the Rumford Committee has placed at our command a brief statement which makes clear the ground of the award.

"'The Rumford Committee voted, June 22, 1893, that it is desirable to award the Rumford medal to Thomas Alva Edison in recognition of his investigations in the field of electric lighting, and they confirmed this vote on October 9, 1893, in the following words: "Voted for the second time to recommend to the Academy that the Rumford medal be awarded to Thomas Alva Edison for his investigations in electric lighting."

"The Committee reached the conclusion expressed by these votes after long deliberation and after careful sifting of all the evidence which was at their disposal in regard to Mr. Edison's claim for priority in the construction of the incandescent lamp, the conception of the central lighting station together with the multitude of devices, such as the three-wire circuit, the disposition of the electric current feeders, and the necessary methods for maintaining the electric potential constant.

"The Committee felt that they could not decide upon Mr. Edison's claim for priority in any particular invention in this new industry. Indeed, Courts of Law, after prolonged litigation, have found it difficult to decide how far Mr. Edison was in advance of contemporary workers. The task given to the Rumford Committee to decide who is most worthy of the Rumford medal, especially in the field of the application of electricity for the production of light and heat, is not an easy one. The number of investigators is now so large that it is no longer possible, in general, for one man to claim to be the first to apply electricity to a new field. The successful application is the result of many minds working on the same problem. Although the Committee did not feel justified in expressing the opinion that Mr. Edison invented the incandescent carbon filament lamp, or that he was the first to arrange such lamp in multiple on the circuit, thus producing what is popularly termed a subdivision of the electric light, or that the Edison dynamo had greater merits than the machine of Gramme and Siemens and others; still, they are convinced that Mr. Edison gave a great impulse to the new industry, and that he was the first to successfully instal a central electric lighting plant with the multitude of practical devices which are necessary. They believe that this impulse was due to his indefatigable application, to his remarkable instinct in whatever relates to the practical application of electric circuits, and to his inventive genius. They, therefore, have unanimously recommended to the Academy to bestow the Rumford medals upon him, feeling that the work of Mr. Edison would especially appeal to the great founder of the medals—Count Rumford—if he were living.

"The Academy has accepted the report of the Rumford Committee, and has voted to confer the gold and the silver medal upon Mr. Edison. The recipient finds it impossible to be present at this meeting of the Academy, and has requested Prof. Trowbridge to act as his proxy and to receive the medals for him.

"In the name of the Academy, I beg you, Prof. Trowbridge, to accept the charge of conveying these medals to Mr. Edison's hands. It would be most ungracious for us who are assembled in this room, which is flooded by this steady and brilliant electric light, to withhold our personal thanks for what Mr. Edison's investigations and practical activities have done for us all. And, hence, I may venture to say that our thanks and all good wishes are to be conveyed with the Rumford medals."

Prof. Trowbridge replied as follows:—

"Mr. President, and gentlemen of the Academy, I accept the medals for Mr. Edison; and at his request I wish to express his deep sense of the great honour the Academy has conferred upon him. His work in the field of electric lighting has been the subject of prolonged litigation, and at times he has had doubts, in reading the opinions of learned experts, whether his work has been original, or whether he had really contributed anything to the world's progress. The recognition of his labours by the American Academy of Arts and Sciences, regarded by Count Rumford in his gifts as the coequal of the Royal Society of London, is, therefore, especially grateful to him. Acting as his proxy, I thank the members of the Academy for the distinction which they have, by their votes, conferred upon him."

CAUSES OF DEATH IN COLLIERY EXPLOSIONS.

A REPORT, by Dr. John Haldane, on the causes of death in colliery explosions, with special reference to the Tylorstown, Brancepeth, and Micklefield explosions, was published in a Blue-book a few days ago. The report contains a vast amount of valuable information on the composition of after-damp, the action on men and lights of the gases present in, or mixed with, after-damp, the action of after-damp, heat and violence, along the track of an explosion, the distribution of after-damp and other gases in a mine after an explosion, the distribution of smoke in underground fires, the positions at which bodies are found after an explosion, and the means of saving life in colliery explosions and fires. To understand the dangers to life after a colliery explosion, and the possibilities of escaping these dangers, it is necessary to have a clear idea of the action, both on men and lamps, of the gases which are likely to be present in the air of the mine. These gases, so far as is known, are carbon dioxide, carbon monoxide, nitrogen, fire-damp, and sulphurous acid. Oxygen may be deficient or absent. Dr. Haldane discusses the effects of these gases *seriatim*, and the information he brings together, as well as his own careful observations, should be valued by colliery managers, while it will certainly interest chemists and physiologists.

In the case of the Tylorstown explosion, which, Dr. Haldane says, was evidently propagated through the three pits by coal-dust, fifty-seven men were killed. Of this number fifty-two, or 91

per cent. of the whole, were killed by after-damp, the remainder being killed instantaneously by violence. In nearly every case of death from after-damp, the parts of the skin or mucous membrane through which the colour of the blood could be observed, had a red or pink colour, instead of being leaden-blue or pale, as is the case in death from any other cause. This reddening, as seen in the face, hands, &c., often gave the bodies an extraordinary appearance of life. There seemed to be only one cause which could account for the carmine red colour of the blood, namely, the presence of carbon monoxide. To make certain, Dr. Haldane examined the blood from two of the bodies on the spot, by means of a spectroscope, and he found that not only was carbon monoxide present, but that the hæmoglobin was nearly saturated with it. A quantitative determination proved that in both bodies the hæmoglobin was 79 per cent. saturated. This result is of special interest, as it shows, for the first time, the percentage saturation of the blood at the moment of death from carbon monoxide poisoning.

The recognition of carbon monoxide in the air of mines is, as Dr. Haldane points out, a matter of much practical importance, and many lives have been lost through ignorance of the fact that the lamps, to which miners trust for the recognition of other gases, give no *direct* indication of carbon monoxide. A simple test, which there is every reason to think might be successfully introduced, is suggested: it is to observe the symptoms of a mouse or other equally small warm-blooded animal, when exposed to the doubtful atmosphere. In small animals the rate at which the blood becomes saturated with carbon monoxide is far more rapid than in man; hence a small animal, such as a mouse, shows the effects of the gas far more rapidly than a man. Practically speaking, the condition of a mouse which has been for a very short time in a poisonous percentage of carbon monoxide, indicates what will be the condition of a man carrying it after a much more prolonged stay in the same atmosphere. With a man at rest it takes about twenty times as long for the man as for the mouse to be distinctly affected by the gas. Dr. Haldane's experiments show distinctly how valuable the indications given by a mouse, or other small animal, would be to men exposed to danger from after-damp. It is therefore suggested that a few white mice might easily be kept for this purpose in the engine-room at the top of the downcast shaft, and be taken down in small cages by the rescue party.

Another point to which attention may briefly be directed is the colour-test described by Dr. Haldane for use in post-mortem examinations as a criterion for carbon monoxide poisoning. A drop of the blood of the subject is diluted with about 100 times its volume of water, and is compared with a solution of normal blood, and with a similar solution saturated with coal-gas. According to the percentage saturation of the sample of blood under examination, the tint of the first solution will approach to that of the normal blood, or of the blood saturated with coal-gas (that is, with carbon monoxide), and a rough estimate may be made of the percentage saturations. The test is said to be more delicate than that with the spectroscope.

INDIVIDUALITY IN THE MINERAL KINGDOM.[1]

IT might be expected of a new Professor that in his inaugural address he should avail himself of the possibly unique opportunity of an audience, and should give some account of his science and of the manner in which he proposes to teach it. In that case he would doubtless claim for his own subject that it is the most fascinating and the most important of all branches of human knowledge; he would doubtless, also, proceed to prove, to his own satisfaction, that it should be a necessary feature in any system of education.

It is well known that every specialist has an exaggerated view of the importance of his own subject; a view which is no doubt largely due to his ignorance of all others. I am deeply conscious of sharing this failing, and therefore do not propose to give any laboured account of mineralogical science; instead of stating exactly what in my opinion should be taught in this university, I will rather state presently what I think should not be taught; instead of attempting to *prove* that mineralogy possesses a true educational value, I will assume that this may be accepted without further argument from the very fact that it is recognised by the University.

[1] An inaugural lecture delivered at the University Museum, Oxford, by Henry A. Miers, F.R.S., Waynflete Professor of Mineralogy.

Perhaps none of the sciences is more of a special subject than mineralogy, in this sense—that it is familiar to few besides those who have made it their particular study; for this reason I may be pardoned if I assume total ignorance on the part of my hearers, and begin by removing a confusion which may possibly exist in the minds of many.

Mineralogy is not crystallography. Mineralogy is the study of minerals in all their relations, and from every point of view; it is a branch of natural history; the study of one class of natural objects, namely, all the inorganic parts of the earth, which we are accustomed to class together as the Mineral Kingdom. Crystallography, on the other hand, is a distinct science, and is the study of matter in the crystalline state, not being by any means confined to minerals; it is, like physics, or chemistry, or geology, one of the sciences whose aid is invoked in the study of minerals.

Since, however, the finest and most interesting examples of crystals have been found in the mineral kingdom, this study has been, by common consent, annexed by the mineralogist, and instruction in crystallography has been left entirely to him. The result has been in some ways disastrous; crystallography is in reality as essential to the student of chemistry or of physics as it is to the mineralogist, and yet remains in general a sealed book to them. They have been reluctant to go to the mineralogist for information, and consequently they have failed to make the acquaintance of crystallography. In this connection I may quote the forcible words of Mr. Lazarus Fletcher: "It seems obvious," he says in an address delivered a few years ago, "that in a satisfactory system of education every chemist should be taught how to measure and describe the crystalline characters of the products which it is his fate to call into existence. A knowledge of the elements of crystallography, including the mechanics of crystal-measurement, ought to be made a *sine quâ non* for a degree in chemistry at every university."

To this I would add that crystallography is not merely a matter of theoretical interest to the chemist, but is absolutely essential for the practical determination and description of any compound. It will scarcely be believed that there is only one teaching institution in the British Isles where crystallography forms a necessary part of the chemical student's course, namely the Central Technical College in London, where I was invited some years ago by Prof. Armstrong to found a class in the subject, and where excellent work is now being done by Mr. Pope. That it is found necessary to insist upon this study in a technical college of all places in the world is surely a remarkable confession that this, like every pure science, is far from being devoid of practical application.

If we turn now to mineralogy proper, the practical value of this science is obvious without any explanation.

In mining and metallurgy we have subjects of vast commercial importance in which a knowledge of scientific mineralogy is most desirable.

In particular it would be a great advantage to this country if all who are sent out to hold official positions in new or distant lands, could receive some previous instruction in the study of minerals which are of economic importance. We should not then hear of ruby companies formed through sheer ignorance to exploit what subsequently proved to be red garnets, neither would valuable ore deposits be overlooked for years simply because no one among the early settlers was familiar with the aspect of the common metallic minerals. I have no doubt that a course of lectures upon the detection of gold, silver, and precious stones, would prove attractive even in Oxford in these days of mining adventure and speculation, and I would not deny that they might be of some service to those whose future work lies in India or the colonies, or to those who travel in little-known regions. But I feel very strongly that our business here is with general education, and that the later the date in any educational system to which extreme specialisation or technical training can be postponed the better it will be for the student.

For this reason mining and metallurgy, which belong to technical education, have in my opinion no more place in such a university as this than any other branch of industrial or applied science. We do not seek here in the matter of practical engineering to compete with the great engineering workshops, or in the matter of clinical instruction with the great London hospitals; and in the same way, we should no more expect or desire to compete here with mining or metallurgical schools than to teach the jeweller's art.

A university can best serve the cause of technical education

by teaching precisely those features of any science which can not well be learnt in later life, and yet are the very foundation of practical knowledge; to the engineer his abstract mathematics and physics, to the medical man his physiology and comparative anatomy. Nothing can better illustrate the enormous value to the manufacturer, for example, of a sound training in pure science than the manner in which Germany has taken the lead in certain chemical industries owing to the excellent scientific instruction received at the universities by the men employed in those industries. Or, to take another instance, it has been confessed by the electrical engineers that the marvellous rapidity with which their industry has grown is largely due to the fact that the mathematical theory had been mainly elaborated before electrical science found its application; there can be no doubt that years of blundering were saved by this fact, for the form and structure of the mechanism required could be almost from the first worked out by well-established principles instead of blind trials.

In the same way I believe that the study of scientific mineralogy has a very considerable value, both educational and practical.

For the successful pursuit of this science a student must combine no inconsiderable knowledge of chemistry, physics and crystallography, and must therefore be to some extent familiar with certain branches of mathematics; if he is further to study the interesting problems of the origin, growth and changes of minerals, he must also be acquainted with the kindred science of geology. There is no fear lest a student of mineralogy should too early become a specialist; as a branch of natural history his science encourages habits of minute observation, as an experimental science it involves accurate physical and chemical work. I am speaking, it will be understood, of scientific mineralogy, the study of the nature and properties of minerals in themselves quite independently of their uses and applications; one who is a master of these matters will not be slow to find the applications.

My predecessor in this chair always set before himself this high ideal, and during a period of forty years endeavoured to kindle among those who attended his lectures an interest in the more purely scientific aspects of mineralogy. As one of his pupils who, having conceived some degree of enthusiasm for the subject, was greatly encouraged by his inspiration, I am glad to have this opportunity of acknowledging my gratitude to Prof. Story-Maskelyne for directing the thoughts of his students in the ways of pure science: I believe it to be the proper course to pursue in the higher teaching at a university.

In this connection I should have been glad to devote the present address to the elucidation of a certain feature in mineralogy which has an educational interest; the fact, namely, that the order in which a subject can best be unfolded before a student's mind is very satisfactorily marked out by the historical development of the subject; that a profitable course of teaching is suggested by the history of a science; and that the order in which problems have presented themselves to successive generations is the order in which they may be most naturally presented to the individual.

It is a principle which comes out very forcibly in the case of mineralogy, and it may, for aught I know, be equally characteristic of other sciences.

First would come the examination of stones by all sorts of simple means; the study of the external characters by which they may be recognised; their colour and lustre; their hardness and weightiness; the methods of recognition employed by the miner; the system of study, in fact, which prevailed in the early part of the century, when the genius of Werner drew students from all parts of Europe to the Mining Academy of Freiberg: a system known as the natural history method. This is an exercise admirably adapted to train the faculty of inquisitive and careful observation in the schoolboy, and in my opinion should be unnecessary in the higher teaching of the science, although it does in an incongruous manner survive therein throughout the German and other universities.

Next, by a transition through the simpler chemical tests, the learner is led to the refined chemical analysis of minerals; a study to which far too little attention is paid at the present day, yet one from which the most fruitful results are to be expected.

Finally, as an inquiry suitable for the most advanced students, follows the investigation by exact methods of the internal structure and constitution of minerals; leading to such researches as are now being prosecuted in Oxford with remarkable success by Mr. Tutton.

Nothing can be more suggestive, from the educational point of view, than the curious history of mineralogy. An excellent account of the early phases is given in the "History and the Philosophy of the Inductive Sciences" of Whewell, who was, it will be remembered, Professor of Mineralogy at Cambridge before he became Professor of Moral Philosophy. But to dilate on these matters would be to do what I have already undertaken to avoid, to celebrate the educational virtues of my own science.

In choosing a subject to which I could more particularly devote an inaugural lecture, I have thought that one which is both interesting and suggestive, even from the scientific point of view, is to be found in the beauty of minerals. No one can glance through a collection of minerals, such as that which adorns this museum, without being impressed by their varied beauty of form and of colour; no one can read what has been written on the subject by Ruskin, without feeling that in their æsthetic aspect they possess a singular fascination. We are perhaps more familiar with them when they have been wrought into beautiful objects by the art of man; the beauty of marble and serpentine, of malachite and lapis lazuli, among decorative stones; that of sapphire and emerald and opal, among jewels; or of onyx and agate, among the less precious gem stones, is known to all. Yet their beauty is mainly that of the minerals themselves, and the hand of the artist does little more than make it visible. Few perhaps, save those who have had personal experience among minerals, are aware of their intrinsic beauty: let any visitor to a museum spend one half-hour among the mineral cabinets, and he will find his reward in the purely æsthetic pleasure to be derived from the contemplation of objects unrivalled in beauty of form and colour. The magnificent collection preserved in the British Museum is, of course, that from which the greatest pleasure can be derived; and in that collection there are no more interesting objects than the fine agates and chalcedonies brought together by Mr. Ruskin with the special purpose of illustrating their beauty of colour and structure. But even in a comparatively small collection like that of our university, there is much that will attract and gratify the eye.

Confronted by this wealth of beauty and interest, the reflective mind is led to propose to itself the question, What is the origin, and what is the object of all this beauty? what purpose does it serve in the economy of nature? In the beauty of the organic world it is possible to imagine both an origin and a purpose. The origin may conceivably be sought in utility. Even if it be denied that in the organic kingdom beautiful objects, whether plants, animals, or human beings, have become useful because they are beautiful, it may, at any rate, be suggested that they appear beautiful because they are useful. But in the mineral world it is altogether different; these wonderful spars and gems, with their infinite variety of form and colour, their intricate groupings of silky fibres and pearly flakes, may have been for ages hidden in dark recesses of the earth where they have led an unchanging existence; and when they are brought to the light of day for the use of mankind, we can admire their beauty, but we cannot see any purpose for which, or any process by which it has been acquired. It may be answered that herein is no cause for surprise; that there is no reason why inanimate objects should not be both beautiful and interesting in themselves apart from any teleological aspect; that, indeed, it is gratifying to find a branch of natural science into which utilitarian considerations do not enter. This may be so, but nevertheless the fact indicates a very remarkable distinction between minerals and other natural objects.

Let us pursue to its conclusion the inquiry which we have provoked, and see whither it leads us.

In the first place, I would point out that the distinction relates not only to the beauty, but to all the properties of minerals; we may equally inquire about them: What is their origin and what is their object? What purpose do they serve in the economy of nature? They have not been acquired by selection, they do not impart any advantage to the mineral itself.

The contrast between minerals on the one side, and animals and plants on the other, is very obvious. There is with the former no change or development, neither progress nor degeneration; no survival of the fittest, no variation of characters. They are perfect and complete, each in itself, immutable and immortal. No struggle for existence takes place in the mineral world as it does among the individuals of the animal and vegetable kingdoms.

It may be answered that this is natural, for such individuals do not exist in the mineral kingdom. In other objects which

possess no individuality there is also no progress, and it is absurd to look for any development among ores, and stones, and rocks. That, however, is not so obvious.

Individuals exist in the mineral kingdom just as truly as they exist among animals and plants; each crystal is a distinct individual, capable of growth by itself, and independent of its fellows; each pursues its own existence; it is even in a sense capable of multiplication, for if a crystal growing from solution be broken in two, each half continues to grow as a distinct individual resembling in all respects the parent crystal.

Mutilate a growing crystal by breaking away one of its corners or edges, it will heal the fracture, restore the missing fragment, and become again a perfect crystal; thus asserting its individuality in an even more persistent manner than many a living organism. The experiment is one which may easily be performed with a crystal of alum.

Hence if a definition of life, or a distinction between organic and inorganic be based upon individuality, as it often has been, it will be exceedingly difficult to exclude crystals. This is precisely what many philosophical writers have found. One or two examples will suffice.

Schopenhauer, for instance, after stating that "in the inorganic kingdom of nature all individuality disappears," is obliged to confess that "the crystal alone is to be regarded as to a certain extent individual"; "in the forming of a crystal we see as it were a tendency towards an attempt at life." Having made this admission he goes on to say: "The crystal has only one manifestation of life, crystallisation, which afterwards has its fully adequate and exhaustive expression in the rigid form—the corpse of that momentary life." There is a constant tendency among philosophical writers to suggest that this individuality implies some relationship between life and crystallisation.

To take another illustration: St. George Mivart says that "in crystals and such forms as dolomite and spathic iron we have an adumbration of organic forms." There is a dubiously expressed feeling, even among writers upon evolution, that crystals may to some extent bridge over the great chasm between living and non-living objects.

Most striking and most surprising of the utterances upon this subject which I have encountered, considering its author, is a remark by Huxley in an article upon the origin of species, in which he says:—

"The inorganic world certainly has its metamorphoses and, very probably, a long Entwickelungsgeschichte out of a nebular blastema. Who knows how far that amount of likeness among sets of minerals in virtue of which they are now grouped into families and orders, may not be the expression of the common conditions to which that particular patch of nebulous fog which may have been constituted by their atoms, *and of which they may be in the strictest sense the descendants*, was subjected?"

What we are really led to see when we pursue further the comparison between minerals and organisms is not a resemblance, but an irreconcilable difference.

In the mineral world the forces of nature act upon the individual without producing any modification.

It is true that by chemical processes a crystal of olivine may have some of its constituents taken from it, and others added to it, whereby it becomes a totally different mineral, serpentine. Or by exposure to the air, a crystal of felspar is converted into crystals of a totally different mineral, china-clay; but until it is destroyed, there is no change or progress of the individual. Each remains, like Bishop Blougram, "calm and complete, determinately fixed, to-day, to-morrow and for ever." There is no response to external stimulus, no adaptation to environment.

The properties, the form, the beauty of living beings are due to continual interaction between external forces and the organism itself. In the organic world the teleological aspect, I imagine, can never be lost from sight; each individual works for its own salvation; unceasing change involves either unceasing progress or degradation. With the mineral this is not so. A crystal of natural quartz has doubtless been the same and has possessed the same properties for countless ages.

In an ever-changing world the crystal is a type of unchanging constancy—its properties remain as permanent as those of the very elements themselves.

The crystal and the organism differ herein, that in studying the latter we have to take into account not only the unknown properties of the organism itself, but the nature of its environment and the character of the forces to which it is subjected; whereas in studying the mineral, we find that its properties express only the nature of the crystal in itself, and are therefore the same whatever may be the conditions of its growth and existence.

When we pass from the crystal even to other inanimate objects, this is no longer the case; the beauty, the form, the characters of any other natural objects are the result partly of their inherent properties and partly of the forces which act upon them. They have been, to some extent at least, moulded by their environment. The form of a mountain is due partly to the nature of the rock of which it consists, partly to the action of the wind, the water, and the weather to which it is exposed. The curve of a coast-line and the contour of its cliffs are to be attributed partly to the durability or the weakness of the chalk or the slate of which it is composed, but partly also to the sweep of the prevalent currents, the direction of the winds, and the rise and fall of the tide.

In no character is this more conspicuous than in symmetry of form and character.

The symmetry of living things is obviously due largely to their environment or to their movement. The symmetry of a tree depends upon the fact that the conditions under which a root grows are different from those which prevail where the branches spread; the symmetry of a fish is intimately connected with the fact that it swims in one direction; the bilateral symmetry of a man can be, I presume, referred to a similar cause. There is no inherent symmetry which is absolutely independent of external force. Vary the conditions, and the symmetry of the organism is varied in response. But in the mineral it is otherwise—the symmetry is essential and inherent; it belongs to the mineral quite independently of external forces. In the study of crystals we are in an altogether unique manner brought face to face with the nature of the thing in itself; surely an uniquely interesting subject for study.

But the contrast can be pursued still further.

The symmetry of crystals is expressed not only in their external form, but in all their properties internal as well as external. They have been the object of much attention on the part of careful experimentalists using the most refined methods of modern physics, and the result has been to establish this fact in the most unmistakable manner. Their symmetry is one not only of external form, but of internal structure. Further it is of a peculiar character, which entirely differentiates crystals from all other things animate or inanimate. It absolutely distinguishes the crystalline individual from the organism. No crystal has the symmetry of any organism, no organism has the symmetry of any crystal.

The latter has recently been the subject of much geometrical investigation, which is probably unknown to others than mineralogists, and a very interesting and suggestive discovery has been made by geometers working independently in Germany, France, Russia and England. The physical study of crystals, their action upon heat, light and electricity, has disclosed another remarkable feature characteristic of them. They are without exception homogeneous. At any point within a crystal its properties are absolutely the same as those at any other point within the same individual. This must be due to homogeneity of structure.

Just as a man walking in an orchard of identical trees planted in a regular geometrical manner, the Roman quincunx for example, would not be able to distinguish one part of the orchard from another by reason of its homogeneity, so we must imagine that Clerk Maxwell's demon, able to transport himself from one point to another within a crystal among the crowd of molecules, or particles, or whatever they may be of which it consists, would not be able to distinguish the one spot from the other.

The geometricians have therefore inquired in what manner such a homogeneous structure can be symmetrical.

In other words, if you take an infinite number of identical things, no matter what they be—molecules, portions of matter, systems of forces, or anything else—and range them side by side, either parallel to each other, or facing different ways, or turned inside out; provided only they are so arranged that the distribution at any one part of the mass is the same as at every other part, what will be their symmetry? This is a purely geometrical problem. The solution leads in the most remarkable way to precisely that sort of symmetry which is characteristic of crystals and of nothing else. Hence it follows that the symmetry of crystals results from their homogeneity, and is not an independent feature.

The result of our inquiry has been, therefore, not to suggest

any fanciful resemblance between life and crystallisation, but to disclose a fundamental difference; not to bridge over the chasm between animate and inanimate objects, but to widen the gulf.

Crystals are symmetrical individuals by virtue of their homogeneity. Organisms cannot be homogeneous in the same sense, or they would possess the symmetry of crystals. One is led to conclude that the organic individual is never homogeneous, but consists of parts which are essentially different, just as the head is different from the body, the leaf from the stem, or the shell from the kernel.

This I imagine to be the result to which biologists have been led by quite independent reasoning: every organic individual, even the simplest possible individual, the cell, whether animal or vegetable, consists of parts which are different; a nucleus, for example, and something distinct from the nucleus.

We may even proceed a step further, for more is implied in this homogeneity than mere similarity of parts. It is also necessary that the parts should not change places. A gas may be homogeneous by virtue of the rapid and irregular movements of its particles; it may be the same at every point, because it is throughout devoid of any orderly arrangement. But this is not the sort of homogeneity which leads to crystalline symmetry. In the case of crystals there can be no taking the average of crowds of irregularly moving particles, such as forms the basis of the kinetic theory of gases; there can be no talk of a drifting of Lucretian atoms, although this was actually put forward as a theory of crystal structure some years ago.

Lord Kelvin's Boyle lecture on crystal tactics, which was delivered in this very room three years ago, dealt with these subjects, and it will be remembered that a crystal was in that lecture regarded as constructed of a number of bodies placed side by side in regular order, and all facing the same way. There can be no doubt that the ultimate particles of a crystal are really in motion, but their motions must be so circumscribed that none encroaches upon its neighbour, and the crystal may therefore be regarded as constructed of immovable units. In contrast with this, I imagine that any organism, even any organic cell, consists of parts which are not only different, but possess differential motions: this fact is indicated, I presume, by the life of any organism, and its growth by intussusception.

Our final conclusion is, therefore, that the symmetry of a mineral differs entirely from that of an organism, and is due to its homogenity and the fixity of its parts. We have been led to something resembling, in some degree, the Homœomeria of Anaxagoras.

It is remarkable that the earliest writer concerning minerals, whose works have survived, uses language which might almost be applied to the discoveries of yesterday; Theophrastus, in his treatise on stones, says that the crystal must be regarded as formed by the concretion of matter pure and equal in its constituent parts, ἐκ καθαρᾶς τινὸς συνεστάναι καὶ ὁμαλῆς ὕλης.

Among modern writers, Herbert Spencer has most explicitly stated that there is some such distinction between living and non-living things. He says: "Matter has two solid states, distinguished as colloid and crystalloid, of which the first is stable and the second unstable. Organic matter has the peculiarity that its molecules are aggregated into the colloid and not into the crystalloid arrangement." This almost amounts to saying that matter which lives cannot crystallise, and that crystallisable matter cannot live.

You will now see that the inquiry with which we began has led us far from our starting-point, and that, under the guise of some reflections upon the beauty of minerals, I have really been inflicting upon you a dissertation upon one of the most abstruse problems of mathematical crystallography—that concerning the ultimate structure of crystals.

You will also see that having proposed the question—What is the origin and purpose of mineral beauty?—I have not been so foolish as to attempt an answer, or to explain why minerals are beautiful, but have merely asserted that their beauty, like all their other properties, cannot have been acquired, and that in this they differ from living things.

My object in venturing on this difficult subject was two-fold. In the first place, I was anxious to show that mineralogy, taken even on its most abstract and most highly specialised side, overlaps other sciences, even biology, with which it might be expected to possess absolutely nothing in common. It brings us face to face with problems relating to the nature of life. Those who study the nature of living things cannot afford to ignore the nature of crystals, any more than those who study the nature of crystals can ignore that of living things.

If to the chemist and physicist some knowledge of crystallography is an absolute necessity, to the biologist it is at any rate a matter of interest.

Those who heard Lord Kelvin's Boyle lecture will have realised both the importance and the difficulty of these speculations relating to the ultimate structure of crystals; speculations which have attracted the keenest interest among many acute thinkers.

It is often forgotten that the earliest scientific work of the great Frenchman, whose name is associated with some of the most magnificent biological discoveries of the age, was in this direction. Pasteur was, at the very outset of his career, attracted by the relation between crystallisation and life. He imagined that in a peculiar mode of symmetry which he discovered in certain crystals, he had found an essential difference between living and non-living material, and that only such crystals as present this particular symmetry are the products of life. It has now been proved that such a symmetry is one which results from crystalline homogeneity, and is therefore proper to crystals; but the interesting fact remains that Pasteur entered upon his study of organisms by the way of crystallography, and that the one was inextricably bound up with the other.

Buckle saw in the history of mineralogy the strongest confirmation of his own views upon organic life. He regarded the early discoveries of the great French mineralogist Haüy, concerning the form and structure of crystals, as one of the most important contributions "to the magnificent idea that everything which occurs is regulated by law, and that confusion and disorder are impossible." Referring to the remarkable power possessed by crystals, in common with animals, of repairing their own injuries, he says: "However paradoxical such a notion may be, it is certain that symmetry is to crystals what health is to animals. When therefore the minds of men became familiarised with the great truth that in the mineral kingdom there is, properly speaking, no irregularity, it became more easy for them to grasp the still higher truth that the same principle holds good of the animal kingdom."

And this leads me to the second reason which I had for selecting my subject, namely, the excellent illustration which it affords of the manner in which each branch of human thought not only overlaps every other, but requires its support.

If philosophic writers can illustrate their views by misleading statements, it is because their illustrations are drawn from subjects with which they have little personal acquaintance, and because they have not consulted those who have made a special study of such subjects. It seems to me that here in Oxford, above all places, more might be done in the matter of mutual assistance, and I am thinking not so much of the aid which might be given by science to philosophy, as of the benefits which philosophy might confer upon science.

I have chosen for my text an instance in which philosophic writers have confused two very different things—the individuality of organisms, and the individuality of crystals, owing to their imperfect acquaintance with the latter. It would have been much easier and far more amusing to select instances in which the scientific specialist has fallen into worse confusion owing to his want of philosophic training.

In Oxford, with our magnificent school of Literæ Humaniores, it seems disastrous that the science student should not receive some of the crumbs that fall from her bounteous table—some encouragement to that philosophic habit of thought in which he acquires far too little training. I can only speak as a specialist, but with the knowledge of what my own subject has suffered through this need, and with the suspicion that this is equally the case with others. It is not for me to suggest how such an object could best be attained; but even if questions were asked in the final school of natural science which would encourage attendance at certain lectures on philosophy, I believe that science students would gain much thereby. It would, no doubt, be equally profitable for the philosophic student to gain some insight into the matters and methods of modern science.

I will conclude by quoting what Goethe has said about crystallography. "It is," he says, "not productive; it exists for itself alone, and leads to no results. The mind derives from it within limits a certain pleasure of satisfaction; its details are so manifold that it may be said to be in exhaustible." "For this reason," he adds, "it has powerfully attracted the acutest intellects, and has kept firm hold upon them."

As regards the want of practical application in this science, the words of Goethe are no longer true. Elsewhere he says: "There is a flavour of the monk or the old bachelor about crystallography, and therefore it is self-sufficient. Practical application in life it has none; its rarest objects—the crystallised precious stones—have to be cut and polished before we can adorn our ladies with them." But you will remember that crystallography means now much more than the study of external form; what is done by the lapidary is really much what is done by the scientific investigator—the result in both cases is to reveal the inherent but hidden beauty of the crystal.

It is, however, very true that there is a self-sufficiency about the science, and for a reason which I have already indicated: crystals can be considered as things which exist for themselves, since their nature is independent of their surroundings.

The philosophic contemplation of these beautiful and unchanging objects among the fleeting scenes of a restless world, does bring with it a philosophic content. Nowhere is the evidence of the permanent order that prevails in nature written in more lustrous and indelible characters than in the mineral kingdom.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE University of Utrecht has just celebrated its 260th anniversary by a series of brilliant *fêtes*.

MR. JOHN R. FELLOWS, of New York City, has given 5000 dols. to Notre Dame University to found scholarships.

THE University of Virginia, which suffered serious damage by fire last autumn, is being rebuilt on the plans of its founder, Thomas Jefferson, friends having subscribed a fund of 250,000 dols. for that purpose.

DR. FRANK P. GRAVES, of Brooklyn, has been unanimously elected president of the State University of Wyoming, located at Laramie. President Graves was born in 1869, and is probably the youngest college president in America.

THE *Electrical Review* states that the Baden Chamber has voted £30,000 to the Technical High School at Karlsruhe, to build a new electro-technical institute. The whole cost of the building projected, exclusive of the cost of the land, is estimated to be about £25,000. The building is to be commenced immediately, and it is expected to be ready for occupation in two years.

THE following are among recent announcements:—Dr. Paul Eisler to be professor of anatomy in the University of Halle; Dr. L. Joubin to be professor of zoology in the Faculty of Science at Rennes; Dr. H. Prous to be professor of zoology in the Faculty of Science in Lille; Dr. J. A. Wislicenus to be professor at the School of Forestry at Tarandt; Dr. G. Frege to be professor of mathematics at the University of Jena; Dr. H. Klinger to be professor of pharmaceutical chemistry in the University of Königsberg, and Dr. Scholl to be assistant professor of chemistry at Karlsruhe.

FOR the evening exhibitions in science and technology offered for competition by the Technical Education Board of the London County Council in April last, and the awards of which have recently been published, 285 candidates entered as compared with 256 last year. There is a similar increase in the number of awards, there being eighty-eight as compared with seventy-seven last session. The examiners' report: "The most noticeable feature was that the performance of candidates who selected such practical subjects as building construction, machine construction, plumbing, metal plate work, &c., was greatly superior, as a rule, to that of candidates who selected branches of pure or experimental science such as mathematics, physics, chemistry, &c." The second conspicuous fact brought to light is the complete want of ability on the part of most of the industrial candidates to deal with the simplest applications of arithmetic to their own trades. This is an old complaint of teachers of technical subjects, and the pity is that it seems as just now as ever. The children from elementary schools leave off their tuition with no knowledge of the principles of arithmetic, though some of them are experts in working ordinary "rules" as they learn to call them. The majority of the successful candidates consist of men engaged in engineering, building, carpentering and plumbing trades. It is to be hoped that one result of their work during the coming session will be to introduce them to those general principles of science on a knowledge of which a successful career in their various avocations most certainly depends.

A BRIEF history of the City and Guilds of London Institute has been received. A glance through the pamphlet should be enough to make members of the Corporation and Livery Companies of London proud of the part they have played in the advancement of technical education in this country since 1876, when, at a meeting of representatives of Livery Companies, it was resolved: "That it is desirable that the attention of the Livery Companies be directed to the promotion of education not only in the metropolis but throughout the country, and especially to technical education, with the view of educating young artisans and others in the scientific and artistic branches of their trades." It was this resolution which led to the foundation of the Institute in 1878. A few years later the Central Technical College—than which there is no more efficient institution for teaching the relations of science to industrial processes—was established. Other Colleges connected with the Institute are the Technical College, Finsbury, the South London Technical Art School, and the Leather Trades School. A very important part of the Institute's work consists of the technological examinations. These examinations have become a powerful agency in encouraging the establishment of technical schools and classes throughout the country, in assisting County Councils and other bodies in the organisation of their local schools and classes, and in securing the useful expenditure of the grants placed at their disposal under the Local Taxation Act, 1890. In 1881 the number of students in attendance at these classes was only 2500, but last year it reached 24,920. The Institute also takes part in establishing and assisting experimental classes in manual training, wood-work and metal-work, cookery, laundry-work, and housewifery, for boys and girls in elementary schools. For this provision and organisation of technical education in the metropolis and in the provinces, the total amount subscribed by the Livery Companies during the past eighteen years is, in round figures, £480,000, of which £150,000 has been expended on buildings and equipment, and the remainder on maintenance, scholarships, prizes, and grants-in-aid. The splendid work done by the various branches of the Institute more than justifies this expenditure.

ON Friday last the Prince of Wales was installed as Chancellor of the National University of Wales; and a large and brilliant company assembled at Aberystwith to witness this crowning of the movement for which educational pioneers in Wales have worked so zealously. After the installation, honorary degrees were conferred upon the Princess of Wales, Mr. Gladstone, Lord Herschell, and Lord Spencer. The three colleges comprised in the new University—Aberystwith, Cardiff, and Bangor—have all been founded within the last five-and-twenty years, and sums amounting to nearly £200,000 have been subscribed to support them. The Welsh people have from very early times shown a desire for knowledge, and now they have a truly national University they will doubtless take still greater pride in developing their heritage. The Vice-Chancellor, Principal J. Viriamu Jones, F.R.S., told the history of the foundation of the University to the Welsh National Society of Liverpool in November last, and a copy of his address, which is published at the offices of the *Western Mail*, Cardiff, was received a few days ago. The need for the University definitely emerged from a proposal adopted by the Cymmrodorion Section of the National Eisteddfod in 1887, that teachers in elementary schools should be trained at the University Colleges. The need was again felt when the Welsh Intermediate Education Bill became law in 1889, for a question which had to be considered in connection with the Bill was the nature and constitution of the authority to which the work of inspecting and examining the intermediate schools should be committed. For these reasons, and because educational pioneers in Wales felt that the existence of a national University was essential to the vitality of the colleges, the foundation of such a University was urged nine years ago, and now what was then ideal has become a fact. Some remarks by Principal Jones on the functions of a teaching University such as that of Wales are not without interest to those who cherish the hope that a teaching University of London may eventually be established. He says:—"It is certainly part of the ideal of any university institution that its professors should be leaders in the departments of scholarship or science which they profess, and that, as such, they should help to frame the courses of study leading to graduation.

Colleges incorporated in a teaching university have this opportunity. Originality of thought has fuller encouragement, and new educational methods have freer play than can possibly be the case in a college of which the students have no other avenue to a university degree than examination by a wholly external examining body like the University of London, however excellent be the conduct of its examinations. An atmosphere of intellectual independence is of the essence of true academic life. The true scholar must breathe it as his native air. And this is not the language of mere theory. It has its immediate practical application on the scientific side. The trained student of science, for instance, entering on manufacturing pursuits should do so with free inquiring eye, ready to believe that it may have been reserved for him to make a discovery of immense value to the industry to which he is devoting himself. I believe that this freedom of spirit is far more likely to be developed and fostered in a teaching university than in a college bound to teach on certain rigid lines laid down by an authority in which it has no part." The first object of the founders of the University of Wales is to ensure that all students of the University shall receive good teaching and thorough training before proceeding to graduation. By this means the University will be made a real force for the advancement of learning in the Principality.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, vol. ii. No. 8, May 1896.—"The Arithmetising of Mathematics" is an excellent translation, by Miss Maddison, of Bryn Mawr College, of an address delivered by Prof. Felix Klein, before the public meeting of the Royal Academy of Sciences of Göttingen, on November 2 of last year. In it Prof. Klein explains his position in regard to an important mathematical tendency which he remarks has for its chief exponent Weierstrass, whose eightieth birthday has been lately celebrated. This tendency he calls the *arithmetising* of mathematics. Like all the author's addresses, this one, now rendered easily accessible to English mathematicians, will repay study.—Next follow three carefully drawn-up reviews, viz. by R. A. Roberts, on a second edition of Darboux's classic treatise, "Sur une classe remarquable de Courbes et de surfaces Algébriques et sur la théorie des Imaginaires." It is matter of regret, Mr. Roberts says, that the author has not devoted some more time to a subject which offered him once such a fruitful field for original investigation.—Then Prof. Böcher examines in detail the "Treatise on Bessel Functions, and their Applications to Physics," by Messrs. Gray and Mathews. He well shows that the writers have by their work filled a real gap in mathematical literature.—In his notice of Miss Scott's "Introductory Account of certain Modern Ideas and Methods in Plane Analytical Geometry," Prof. F. N. Cole states it to be a minor excellence of the book that it is written in the English of English speaking and writing people, *i.e.* there are no abbreviations, and such like, which necessitate constant reference to a "list of signs," &c. He looks upon Miss Scott's performance as a compact, scholarly work on the more accessible principles and methods of modern analytical geometry. "It exhibits to a marked degree that genial breadth of treatment and conciseness which are associated only with mature scholarship and extensive and accurate information." His summing-up of warm approval is that he knows of no introductory work which is better adapted, in the particulars he indicates, for the use of those who desire not merely to learn, but also to master geometry.—Prof. H. B. Newson, in a note on "A Remarkable Covariant of a System of Quantics," calls attention to a covariant of a system of n quantics in n homogeneous variables. He states two important geometric properties of this covariant which, *pro tem.*, he calls the Cremonian. (1) The Cremonian of U, V, and W is the locus of the point (x', y', z') whose first polars with respect to U, V, and W have a common point; the locus of these common points is, of course, the Jacobian. (2) The Cremonian of U, V, and W is also the locus of (x, y, z) the point of intersection of the polar lines of (x', y', z'), with respect to U, V, and W, *i.e.* it is the locus of the point of intersection of the polar lines of the points on the Jacobian. The author gives other results of interest, and hints at an extension of the conception of the Cremonian to spaces of higher dimensions.—Much interesting matter is given in the Notes, and a list of recent publications fills up a big number of 44 pages, in place of the usual 32 pages.

Symons's Monthly Meteorological Magazine, June.—The worst gale of the nineteenth century in the English Midlands (continued). A map is given showing the path of the storm from South Wales to Lincolnshire between 11 a.m. and 4 p.m. on Sunday, March 24, 1895. The average velocity of translation was about sixty miles an hour, and the disturbance appears to have been caused by a subsidiary depression formed over the south of Ireland, during a well-marked cyclone which lay over the northern parts of our islands on the same day. Great disaster was caused along its track, and fourteen deaths were reported. There were also more than a dozen cases of windows and gables being blown *out*, owing to the expansion of air inside the buildings during the passage of diminished atmospheric pressure.—Fog, mist and haze, by a Fellow of the Royal Meteorological Society. This is a continuation of the discussion raised in the preceding number of the *Magazine* (NATURE, June 4, p. 118). The writer agrees generally with the definitions proposed, as a practical scheme, based on a correct view of the phenomena, but he thinks that the difference between fog and mist should not rest upon what can be seen with the naked eye—a test in which two persons would be very apt to disagree.

THE enlarged issue of the *Journal of Botany* still continues to be occupied almost entirely with papers on descriptive botany, and chiefly relating to the flora of the British Isles. In the numbers for May and June, Prof. R. Chodat describes some new species of *Polygala* from South Africa; and Mr. W. H. Pearson a new liverwort, *Plagiochila Stableri*, from Rydal.

THE papers in the *Nuovo Giornale Botanico Italiano* for April, and in the *Bulletino della Società Botanica Italiana*, Nos. 2–4, relate almost entirely to the flora of Italy. In the former, Signor S. Sommier describes and figures an interesting hybrid between *Ophrys bombyliflora* and *O. tenthredinifolia*. In the latter is an abstract of an article by Signor B. Longo, on the mucilage of the Cactaceæ.

Bulletin de la Société des Naturalistes de Moscou, 1895, No. 3.—On considerable perturbations of atmospheric pressure in the year 1887, by B. Sresnewskij. A research into the relations between the said perturbations, the movements of cyclones, and the local weather predictions based on the study of the same; as also their relations, both to the groups of areas of minimal pressure and to the distribution of temperature (in German).—Materials for the Amphibia and Reptile fauna of the Orenburg region, by N. Zarudnyi. List of eleven species of the former, and fifteen species of the latter (Russian).—*Aquila Glitchii*, Severtsoff, a biological sketch, by P. Suschkin, in German, with two plates.—Note on *Posidonomya buchi* of the Balaclava schists in Crimea, by M. D. Stremoouchow, with a plate.—On Russian Zoocecidiæ and their makers, by. Ew. H. Rübsaamen, based on a collection made by Madame Olga Fedchenko and her son Boris Fedchenko. No less than 120 galls and their occupants from various parts of Russia and Caucasia are described.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 11.—"On the Relations between the Viscosity (Internal Friction) of Liquids and their Chemical Nature. Part II." By Dr. T. E. Thorpe, F.R.S., and J. W. Rodger.

In the Bakerian Lecture for 1894 the authors gave an account of their work on the viscosity of some seventy liquids, and they discussed the interdependence of viscosity and chemical composition. In order to render their investigation more complete, they have now made measurements of the viscosity of (1) a number of esters or ethereal salts, and (2) of ethers, simple and compound—groups of liquids, which with the exception of a single member, ethyl ether, have not hitherto been studied by them. The physicochemical relationships previously established made such determinations of special interest, for it was shown that one of the most striking of the various connections traced between chemical constitution and viscosity was the influence exerted by oxygen according to the different modes in which it was assumed to be associated with other atoms in the molecule. The influence which could be ascribed to hydroxyl-oxygen differs to a most marked extent from that of carbonyl-oxygen, and it appeared that ether-oxygen, or oxygen linked to two carbon atoms, had also a value which differed considerably from oxygen in other conditions.

The details of the observations are given in precisely the same manner as in the first paper, and formulæ of the Slotte type showing the relation between viscosity in absolute measure and temperature are calculated for each liquid. The general results of the observations are then discussed in the same manner as in the previous memoir.

The conclusions relating to the graphical representation of the results may be thus summarised. Both ethers and esters give no evidence of molecular aggregation, and conform to the rules that :—

(1) In homologous series, the viscosity is greater the greater the molecular weight.

(2) An iso-compound has a smaller viscosity than a normal isomer.

(3) The more symmetrical the molecule of an isomeric compound the lower is the viscosity.

As regards the esters themselves, it is noteworthy, where the comparison is possible, that :—

(4) Of isomeric esters, the formate has the larger viscosity.

As regards the algebraical representation of the results, it is shown that in the expression $\eta = C/(1 + \beta t + \gamma t^2)$, derived from Slotte's formula :—

(1) In any homologous series, β and γ increase as the molecular weight increases.

(2) Of isomeric compounds, the iso-compound has the smallest coefficient.

(3) Ethyl ether, the symmetrical isomer, has smaller coefficients than methyl propyl ether.

(4) As regards normal isomeric esters, the formate has the largest, and the propionate the smallest coefficients, and the values of the acetate are larger than of the butyrate.

The authors then deal with the relationships existing between the various viscosity magnitudes—the viscosity coefficient, the molecular viscosity, and the molecular viscosity work—(1) at the boiling point, and (2) at temperatures of equal slope, the slope adopted being that employed in their previous paper, namely, 0·04323, and values for the oxygen in three different conditions are given for each system of comparison in the same manner as in their first communication.

Physical Society, June 26.—Captain Abney, President, in the chair.—Mr. F. Bedell read a paper on admittance and impedence. The author discusses the application of the method of "vector diagrams" to the solution of questions connected with alternating currents. He shows how, by a consideration of the loci of the different lines on such a diagram, many problems which require for an analytical solution a lengthy investigation, may be simply and expeditiously solved. Mr. Blakesley asked the author what was his test of resonance? Was it that the primary current and E.M.F. were exactly in the same or in opposite phase? The term resonance was an acoustical one, and he did not see why it should be applied to one particular case in the electrical problem. Mr. Inwards asked what degree of accuracy the author had obtained. The author in reply said that if the applied E.M.F. and the current were brought into phase by means of a condenser in the secondary, then he called that a case of resonance. The agreement between the experimental and theoretical results was generally within from 1 to 3 per cent.—Prof. S. P. Thompson read a paper on the properties of a body having a negative resistance. The author, after showing the consequences which would follow according to the laws of Joule and Ohm if we postulate the existence of a body having a negative resistance, goes on to show how the observations described by Messrs. Frith and Rodgers, in a paper read at a recent meeting of the Society, only prove that that part of the resistance of an arc, which is not constant, is a positive resistance that varies inversely as the current. Since it varies inversely as the current the term dR/dC will be negative, and so will the quantity $C(dC)/dR$, which is what they have tabulated as a negative resistance. That the resistance of the arc itself should vary inversely as the current is natural, for it may be regarded as a column of vapour, the cross-section of which is proportional to the current, and therefore increasing in its conductance in direct proportion to the current. There is no need even to suppose any (distributive) adjuvant E.M.F., which would be the other alternative to the suggestion they have made Mr. Swinburne asked if the numbers on which Messrs. Frith and Rodgers based their arguments were obtained by taking successive readings of a voltmeter. Prof. Ayrton said that what they maintained was, that if the arc acts as if it had a back E.M.F. and a resistance, then the resistance is a negative quantity. In ordinary cases we do not know what really constitutes a resistance, but simply say that a circuit, in which electrical energy is being dissipated at a rate proportional to the square of the current, has resistance. If the loss is proportional to the first power of the current, then we say there exists a back E.M.F. Is it impossible to imagine a circuit in which a loss of electrical energy occurs proportional to the current, and a return of energy to the circuit proportional to C^2? If in a curve showing the relation between V and C you draw a tangent at any point, it is not the tangent of the inclination of this tangent which Messrs. Frith and Rodgers have called the resistance; it is another quantity, which they call the electrical dV/dC. In conclusion the author seems to have based his paper on three misconceptions: (1) That it had been claimed that a negative resistance could exist alone. (2) That the curves given by Messrs. Frith and Rodgers showed that the ordinates were inversely proportional to the current. (3) That what was measured was the geometrical dV/dC. Mr. Frith said that in a paper by Mr. Rodgers and himself, they had defined the resistance of the arc as the ratio dV/dA, where by dV/dA they meant, not what was ordinarily understood by this expression, but the value of the ratio obtained by superposing an alternating current for a direct current arc. In order to show that, in cases analogous with that of the arc, but in which the true resistance can be verified, the electrical dV/dC obtained by superimposing an alternating current gives correct results for the resistance, some experiments have been carried out. In one case a glow-lamp was placed in series with some fifty ampere secondary cells, and a current sent through against the E.M.F. of the cells. The value obtained for the electrical dV/dC agrees very well with the value of the resistance obtained by dividing the P.D. between the terminals of the lamp by the current. At very low frequencies for the superimposed alternating current it is evident that the electrical oscillations would travel along the steady value curve, and this is clearly the meaning of the critical frequency observed with cored carbons, namely, that under the critical frequency the superimposed alternating current travels on the steady value curve, and over that frequency along the line joining the point on the curve and the instantaneous origin.—Mr. Frith exhibited a mechanical model of the arc which he has devised. This model consists of two rods of carbon dipping in two mercury cups which are traversed by the current. The current also passes through a solenoid which attracts an iron core attached to the carbon rods and draws them down into the mercury, thus reducing the resistance of the instrument. Hence it can be arranged so that the P.D. between the terminals decreases as the current increases. With this model it is found that, for superimposed oscillatory currents of such a frequency that the moving parts are not able to follow the changes in the current, the oscillations of the current and of P.D. are in phase, and the electrical dV/dC gives the resistance of the apparatus for various currents. Mr. Carter asked the author how on his vapour column theory he explained the difference in the behaviour of solid and cored carbons. Mr. Enright asked why it was absurd to suppose that a negative resistance could exist. Prof. Ayrton and Mr. Frith had made in their definitions certain restrictions; it ought, however, not to be necessary to make any such restrictions. Mr. Blakesley asked if, since the title of the paper by Messrs. Frith and Rodgers was entitled the "*true* resistance of the arc," it was to be inferred, as the results given were negative, that a negative ohmic resistance existed in the arc. Prof. Thompson's paper appeared to him (Mr. Blakesley) to be rather a mathematical than a physical paper. Prof. Rücker said that the discussion showed that considerable confusion existed, and that the introduction of the term negative resistance only tended to fog matters. It was entirely wrong to argue that because you have a quantity with a positive value, therefore a negative value must also be possible. As an example, take the case of mass. If you defined as a positive mass that which is attracted to the earth, and then found that cork when immersed in water was repelled from the earth, would you therefore say that cork had a negative mass? Is not "negative resistance" a term for which some equivalent could be found which would not lead to confusion? Mr. Hovendon made some remarks on his experiments. The author in his reply said that he did not dispute the accuracy of the results obtained by Messrs. Frith and Rodgers, but it was the interpretation which they had given of their results to which he objected. Mr. Frith now makes a new reservation, namely, that the results depend on the particular

way in which the increment of C and the decrement of V are made. He supposes that if the experiment is made in a particular way a new slope is obtained which is proportional to what we call the true resistance, and hence gets a new definition of the quantity dV/dC. He (the speaker) endorsed all Prof. Ayrton had said as to the interest of the model exhibited. The question is, Is there anything in the arc which acts as a source of energy to the circuit, either as a negative resistance or as an adjuvant E.M.F.? Mr. Frith's experiments do not give us any hint as to the point where the negative resistance occurs, and the absence of any such energy-giving portion of the arc is rendered probable by the fact that the arc itself is hotter than the crater. In reply to Mr. Carter, the anomalies which occur with cored carbons are so great as to prevent any argument being based on their behaviour. The Chairman (Captain Abney) said that the mere fact that the quantity dV/dC had been defined in two distinct ways, showed that the definitions would have to be modified in some way.

Zoological Society, June 16.—Sir William H. Flower, K.C.B., F.R.S., President, in the chair.—Mr. E. E. Austen gave an account of a journey undertaken by Mr. F. O. Pickard-Cambridge and the author up the Lower Amazons, on board Messrs. Siemens Bros. cable s.s. *Faraday*, for the purpose of making zoological collections on behalf of the British Museum. No terrestrial mammals were met with, but observations were made on the two species of freshwater dolphins (*Inia geoffroyensis* and *Sotalia tucuxi*, or *S. fluviatilis*), which are extremely abundant in the Lower Amazons. Among the birds, the only species of special interest collected were a little goatsucker from Manaos, referred provisionally to *Nyctiprogne leucopygia*, and a woodpecker (*Celeus ochraceus*), of which the British Museum previously possessed but two specimens. The reptiles and amphibians met with all belonged to well-known and widely distributed forms, and the chief interest of the collections centred in the invertebrates. Among these Mr. Pickard-Cambridge made a large collection of spiders, including an extensive series of the large hairy Therephosidæ, eleven species of which were pronounced to be new. An interesting collection of the nests of some of these forms was also obtained. Mr. Cambridge likewise secured several specimens of *Peripatus*. Mr. Austen, who devoted himself chiefly to insects, obtained some 2500 specimens of different orders, of which it was expected that a fair proportion would prove to be new. Attention was drawn to some interesting examples of mimicry.—Mr. P. Chalmers Mitchell read a "Contribution to the Anatomy of the Hoatzin (*Opisthocomus cristatus*)." He stated that from the characters of the alimentary canal, the hoatzin might be placed either between the sand-grouse and the pigeons, or between the Gallinæ and the Cuculidæ. He described some interesting individual variations in the condition of the ambiens muscle, and referred to other points in the muscular anatomy.—Mr. G. A. Boulenger, F.R.S., gave an account of the occurrence of *Tomistoma schlegeli* in the Malay Peninsula, and added some remarks on the atlas and axis of the Crocodilians.—A communication was read from Mr. W. Schaus containing notes on Walker's American types of Lepidoptera in the University Museum, Oxford.—Mr. Hamilton H. Druce read a paper entitled "Further Contributions to our knowledge of the Bornean Lycænidæ," in which he referred to about forty species of this family not hitherto recorded from Borneo. A number of these were new, and were now described by Mr. G. T. Bethune Baker and the author.—Mr. F. G. Parsons read a paper on the anatomy of *Petrogale xanthopus* as compared with that of other kangaroos. Dr. J. Anderson, F.R.S., communicated on behalf of Miss M. E. Durham some notes on the mode of swallowing eggs adopted by a South African snake, *Dasypeltis scabra*, as observed in the specimens now living in the Society's Gardens, and illustrated by a series of drawings.—Mr. F. O. Pickard-Cambridge read a paper on the spiders of the family Aviculariidæ taken during the expedition up the Amazons previously described by Mr. Austen.—Mr. G. A. Boulenger, F.R.S., read the description of a gecko which he proposed to refer to a new genus and species as *Mimetozoon floweri*, in honour of Mr. Stanley Flower, who had obtained the specimen at Penang.

Royal Meteorological Society, June 17.—Mr. E. Mawley, President, in the chair.—Mr. H. Harries read a paper on Arctic hail- and thunder-storms, in which he showed that the commonly accepted opinion that hail- and thunder-storms are almost, if not quite, unknown in the Arctic regions is incorrect. He had examined 100 logs of vessels which had visited the Arctic regions, and found that out of that number no fewer than 73 showed that hail was experienced at some time or other. Thunder-storms were not so frequent as hail, but they have been observed in seven months out of the twelve, the month of greatest frequency being August. Mr. Harries is of opinion that the breeding-place of thunder-storms in these high latitudes is in the neighbourhood of Barent's Sea.—A paper, by Mr. J. E. Cullum, on the climatology of Valencia Island, was also read. The observatory at Valencia, which is under the control of the Meteorological Office, is situated on the extreme south-west coast of Ireland, and is almost the most westerly point of Europe. Continuous records from self-recording instruments were carried on from 1869 until 1891, when the observatory was removed to Cahirciveen, and the author gives the results of the observations for these twenty three years.

Royal Microscopical Society, May 20.—Mr. A. D. Michael, President, in the chair.—Mr. E. M. Nelson exhibited and described a small portable microscope, which had been designed by Dr. Ross for the investigation of cases of malarial fever. The President said that the instrument seemed to be very compact, and in this respect would no doubt be found of great value. Mr. J. E. Ingpen wished something could be done in designing microscopes of this kind to get them to fold up a little flatter.—Mr. J. Rheinberg's paper, on an addition to the methods of microscopical research by a new way of optically producing colour contrast between an object and its background, or between definite parts of the object itself, was read by Mr. Nelson.

June 17.—The Rev. Canon Carr, Vice-President, in the chair.—Surgeon V. Gunson Thorpe, R.N., exhibited and described some Rotifera, preserved after Rousselet's method, which he had collected whilst on the China station.—Lieut.-Colonel Siddons, R.A., exhibited and described a portable microscope which he considered met the suggestion offered by Mr. Ingpen at the previous meeting.—Mr. Conrad Beck read the report of the sub-Committee of the Council on screw-tools.

PARIS.

Academy of Sciences, June 22.—M. A. Cornu in the chair. An expression for the skin friction in the irregular flow of a fluid, by M. J. Boussinesq.—Some properties of the primitive roots of prime numbers, by M. de Jonquières.—On the caustic of an arc of a curve reflecting rays emitted by a luminous point, by M. A. Cornu.—On the formation of gaseous and liquid hydrocarbons by the action of water upon metallic carbides. Classification of the carbides, by M. H. Moissan. A *résumé* of the work done by M. Moissan and his pupils upon metallic carbides, together with some remarks on the geological bearing of the results.—Remarks on a work entitled "Microbial and animal toxins," by M. A. Gautier.—Observations on Swift's comet (April 13, 1896) made with the large equatorial at the Observatory of Bordeaux, by MM. G. Rayet, L. Picart and F. Courty.—Dr. Gill was elected a Corresponding Member in the Section of Astronomy in the place of the late Prof. Cayley.—On the zero of Riemann's function $\zeta(s)$, by M. Hadamard.—On the X-rays, by M. C. Maltézos. Some theoretical considerations as to the possible nature of the rays.—An electrolytic method of desilverising argentiferous lead, by M. D. Tommasi.—Magnetic anomaly observed in Russia, from a letter by M. Moureaux to M. Mascart. In the village of Kotchetovka (lat. 51°, long. 6° 8′ east of Poulkowa) determinations of the magnetic elements at fifteen points within an area of one square kilometre gave values for declination varying between +58° and −43°; for inclination, from 79° to 48°, and for the horizontal component, 0·166 to 0·589. The latter figure, which is the highest value of the horizontal component hitherto observed, was carefully controlled by six measurements at neighbouring points, from the results of which figures between 0·48 to 0·58 were obtained.—On the dark blue nitrosodisulphonic acid, by M. Paul Sabatier. By the action of cuprous oxide upon strong sulphuric acid containing a little nitrite, a deep blue colour is produced, the absorption spectrum of which is closely analogous to that produced by Fremy's potassium oxysulphazotinate (nitrosodisulphonate). The same coloration can be produced by passing a current of nitric oxide mixed with air into sulphuric acid saturated at 60° with sulphurous anhydride.—On the preparation of aluminium alloys by a chemical reaction, by M. C. Combes. A mixture of aluminium with a sulphide or chloride is heated till the reaction

commences. The heat evolved during the chemical action is sufficient to melt the alloy formed provided that there is a sufficient difference between the heat of formation of the metallic sulphide employed and that of aluminium sulphide. Alloys of aluminium with nickel, manganese, and chromium were prepared by this method.—On the action of phosphorus on some metallic chlorides, by M. A. Granger.—Measurement of heat of etherification by the action of the acid chloride upon the sodium alkylate, by M. J. Cavalier. A thermochemical study of the reaction between phosphoryl chloride and sodium ethylate.—On the heat of combustion of acetal and monochloracetal, by M. Paul Rivals.—On the thermochemistry of the chloracetic ethers, by M. Paul Rivals. Action of hydrazine upon the glyoxylic acids of the aromatic series, by M. L. Bouveault. The hydrazones obtained lose CO_2 at 180°-200°, giving nearly quantitative yields of the hydrazones derived from the corresponding aldehydes.

$$R(CO_2H).C=N-N=CR(CO_2H)=2CO_2+R.CH{:}N-N{:}CH.R$$

The yield of aldehyde, however, obtained by the hydrolysis of these hydrazones is not good.—On the constitution of inactive campholenic acid, by MM. Guerbet and A. Béhal.—On the nutritive value of flour and on the economic consequences of excessive sifting, by M. Balland.—On the chemical mechanism of the reduction of nitrates in plants, by M. A. Bach.—On the rational denaturation of alcohol, by M. G. Jacquemin. The addition of crude mercaptan to rectified spirit is suggested as a means of rendering alcohol unfit to drink, without interfering with its industrial applications.—On the deep borings at Charmoy (Creusot) and Macholles (Limagne), by M. A. M. Lévy. The first of these borings showed a rise of 1° C. for every 26 metres, the second (Charmoy) giving a rise of 1° C. for every 14·16 metres.—On the region of Diego Suarez (Madagascar), by M. R. Bourgeois.—On the relations which exist between the first segmentation groove and the embryonic axis in Amphibia and Teleostia, by M. E. Bataillon.—Tuberculosis experimentally shown to be attenuated by the Röntgen radiation, by MM. L. Lortet and Genoud.

PHILADELPHIA.

Academy of Natural Sciences, May 19.—The collections made by Dr. A. Donaldson Smith in Western Somaliland and the Galla country, North-eastern Africa, in 1894, were presented to the Academy. Dr. Smith spoke of the physical features of the regions from which the specimens had been collected, and gave briefly some facts regarding the habits of the animals observed by him. The several sections of the collection were commented on by the specialists of the Academy. The mammals are of unusual interest because these alone have not been studied by authorities elsewhere. They embrace fifty genera and about seventy species represented by over two hundred specimens. Seven genera and twelve species are new to American museums. The collection, except the bats, which are being studied by Dr. Harrison Allen, is in the hands of Mr. Samuel N. Rhoads, who will furnish a detailed report on the material submitted to him. The birds have been studied by Mr. Bowdler Sharpe. One hundred and fifty specimens of about one hundred species have been given to the Acadamy. The insects embrace 871 specimens. The Hymenoptera are being studied by Mr. Wm. J. Fox, who has determined eight species heretofore undescribed.—Mr. Henry A. Pilsbry made a communication on the fish-house deposits of New Jersey.—A paper entitled "The Plantstonokrit, a centrifugal apparatus for the volumetric estimation of the food supply of oysters and other aquatic animals," by Dr Chas. S. Dolby, was presented for publication.

May 26.—A paper entitled "Catalogue of the species of Cerion, with descriptions of new forms," by Henry A. Pilsbry and E. G. Vanatta, was presented for publication.—Mr. Edw. Goldsmith reported that a specimen of supposed Guperite from Hawaii had proved on examination to be an amorphous, soluble sulphate of lime. It is deposited in association with sulphur on the margin of the Kilauea crater, and is either ejected from the volcano or formed by the action of the oxygenated sulphur water on associated minerals.—Prof. Edw. D. Cope described a new genus and species of whalebone whale from the Miocene of the Yorktown epoch, under the name *Cephalotropis coronatus*. It was characterised by an elongation of the parietal and frontal bones, and establishes the relation of the group to the Zenglodonts.—Dr. M. F. Ball described a human exancephalic monster born about the seventh month, in which the brain, although extruded, was well developed.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Fourteenth Annual Report of the Fishery Board for Scotland, 1895, Part 1 (Edinburgh, Neill).—19th Annual Report of the Connecticut Agricultural Experiment Station, 1895 (New Haven).—Rheumatism, its Nature, its Pathology, and its successful Treatment: Dr. T. J. Maclagan (Black).—La Vie d'un Homme. Carl Vogt; W. Vogt (Paris, Schleicher).—Nitro-Explosives: P. G. Sanford (Lockwood).—Wayside and Woodland Blossoms: E. Step, 2nd series (Warne).—Geographical Journal, Vol. 7 (Stanford).—Plants of Manitoba (M. Ward).—Coloured Vade-Mecum to the Alpine Flora for the use of Tourists in Switzerland: L. and C. PROFESSOR ROUX'S COLLECTED WORKS.

Gesammelte Abhandlungen über Entwicklungsmechanik der Organismen. Von Wilhelm Roux. Vol. i. Pp. xiv + 816. Vol. ii. Pp. iv + 1075, 10 plates and 33 woodcuts. (Leipzig: W. Engelmann, 1895.)

ALTHOUGH Prof. Roux must be regarded as the founder of that branch of zoological research called "The Mechanics of Development," which has recently become so popular, yet his works are comparatively little known to zoologists in this country; and it will probably occasion a mild shock of surprise to the English reader, to see the two huge tomes which bear Prof. Roux's name.

When, however, one peruses these works, it soon becomes clear, from the numerous complaints on the subject which Prof. Roux makes, that the writer's own countrymen have not been in the habit of reading his publications with that care which their imposing size would seem to demand; and whatever wonder one may feel at this in the first instance, is soon removed when one becomes acquainted with the contents of the volumes. It may be said, we think with truth, that next to the recording of careless observations, the most deadly sin which a zoological writer can commit is prolixity, and it must be confessed that in this respect Prof. Roux sins very badly. The quantity of literature which is pouring in on us is stupendous; it is becoming more and more difficult for a zoologist to keep himself abreast of the times in more than an exceedingly limited department of the subject, and it seems to us that it is the first duty of every writer to put his results as briefly as is consistent with clearness. In justice to Prof. Roux, it should be mentioned that there is in this, as in every "complete edition of works," a good deal of unavoidable repetition, since of course the volumes are made up of separate papers, in several of which the same or similar subjects are treated; but when every allowance has been made, one is obliged to confess that the proportion of theory to fact is enormous, and that no effort is made to put matters in a compact and terse manner.

The first volume may be said to contain Prof. Roux's theory of organic evolution, as well as several applications of it in specific cases. The proper place to commence the perusal is with the second paper; the first paper contains an account of the laws of branching of blood-vessels, which laws are regarded by Prof. Roux as special instances of the general principles deduced in the second essay from a general survey of biological facts.

Prof. Roux first shows the extreme difficulty of accounting by simple natural selection for the innumerable adaptations, carried out into the finest detail, which are met with in all the organs of the vertebrate body. According to this theory, a variation, in order to be preserved, must be of such decided advantage or disadvantage to its possessor as to settle the question of survival. When we find, however, that all over the body secondary blood-vessels are given off at such angles that the blood-current encounters no frictional resistance, that in bones the meshes of the spongy ossification are disposed so as to strengthen the structure only in those directions in which it is apt to be bent, and thus effect the maximum of economy consistent with efficiency; that the fibres of fasciæ are arranged parallel to the directions of tension; how are we to picture to ourselves such arrangements arising from the accumulation of irregular variations? Are we seriously asked to believe that a slight alteration in the direction of the fibres of one of the tendons, or in the angle which a small artery makes with the larger one from which it springs, would determine the survival of an individual? Is it credible that animals are so tremendously hard-pressed for food that such a trifling economy in material would appreciably affect them? Even if we are capable of such confiding faith in the theory, we are met by further difficulties. Suppose, for example, that a better arrangement of the skeletal material in a given bone will save the life of an animal, what right have we to assume that this variation will be accompanied by similar advantageous changes in other organs? Are not the chances a thousand to one, that the advantage which one animal possesses in one organ will be balanced by the advantages which another possesses in another respect, so that natural selection will have no opportunity to heap up variations? It is to be observed that even if we assume that "related parts" vary together, it will help us. For the question s not one of a general change in the character of bones, for instance, all over the body, but of the special adaptation of each bone to the local needs. Further, if we say that at one period in the existence of vertebrates, one organ was of relatively great importance and improved by natural selection, and then another, how are we to suppose that the change from an aquatic to an air-breathing existence took place? Here, as Prof. Roux points out, we must have had simultaneous modifications in almost all the organs of the body: the respiratory and circulatory organs, the limb muscles, the eye and other sense organs, must all have changed at the same time.

It must be admitted that Prof. Roux has brought together a most powerful case against the doctrine of the "all-sufficiency of natural selection," and we feel sure that his arguments will awaken a sympathetic chord in the minds of many, if not most, zoologists, amongst whom there is a general feeling that we want something more than natural selection.

Destructive criticism is, however, always easier than constructive hypothesis, and it seems to us that the hypothesis which Prof. Roux puts forward as supplementary to the ordinary doctrine of natural selection is not by any means satisfactory. Briefly it is as follows. Every cell, he assumes, is made up of various parts capable of assimilation and reproduction (the biophores of Weismann), and it is infinitely probable that the rates of assimilation and reproduction of these parts will not be alike. Hence those which thrive best under the stimuli which are pouring in upon the cell, will increase faster than the others, and gradually squeeze them out of existence, and by this means the most useful cell qualities will gradually be evolved. The same reasoning applies to the cells themselves. We know that in many

organs the old cells are gradually worn out and replaced by new ones. The cells of the formative layer (such as the Malpighian layer of the epidermis) will not be precisely equal in their qualities, and those whose assimilation and reproduction is furthered by the "functional stimuli" (that is, the stimuli, such as light, contact, chemical action, which call forth the performance of the function of the organ as a response) will flourish at the expense of others. The same argument is only capable of a limited application to the case of organs, since different organs fulfil different functions, and one function cannot preponderate at the expense of another without upsetting that balance which is essential to the continuance of life. Nevertheless, that there is some such tendency is shown by the fact that if an organ ceases to perform its function properly (such as occurs, for instance, in the case of the kidney in Bright's disease), it is apt to be pressed upon, and eventually destroyed by, the hypertrophied connective tissue.

It will thus be seen that Prof. Roux's theory, which he calls "the Conflict of the Parts within the organism," is a new explanation of the well-known effects of use and disuse. He points out that it completely differs from the crude mechanical hypothesis put forward by Herbert Spencer in his "Principles of Biology"; this latter, distinguished by Roux as the theory of "Functional Congestion," attributed increase in bulk, due to use, to the increased blood-supply mechanically brought about by increased function. Apart from the fact that increase in bulk in an organ only takes place in those dimensions in which it is called for by its function (thus the epidermis increases in thickness, a muscle in breadth, &c.), whereas increased blood-supply should cause uniform increase in all dimensions, Herbert Spencer's theory is inconsistent with the fact that if the nerves which convey the ordinary stimuli to an organ (such as a salivary gland) are cut, we may have congestion accompanied by degeneration, rather than increase in size.

It must be confessed that there is much about Prof. Roux's theory which induces one to wish that it were true. Apart, however, from the minor circumstance that the assumption of competing parts within the cell is an absolutely unsupported hypothesis, this theory utterly breaks down when we come to consider the question of heredity. Let it be granted that the liver consists of several kinds of cell, some of which perform their function better than others, and thus survive—how are these survivors to impress their peculiarities on that portion of the ovum which is destined to produce the liver in the young animal? It seems to us that before the question of "direct functional adaptation" can be even entertained by zoologists the question of the possibility of the inheritance of acquired variations must be grappled with, and decided one way or the other.

Prof. Roux next passes on to some general considerations on the nature of life and the origin of life and consciousness; he points out that life is not capable of being statically defined; it is, he says, essentially a process, not a series of chemical attributes, and hence it is absurd to suppose that a slight chemical difference is all we have to assume, in order to account for the difference in properties of living and dead protoplasm. The speculations as to the origin of life and consciousness are as fatuous as such theorising usually is, and we think that a little study of elementary psychology would have prevented Prof. Roux giving vent to his extraordinary ideas as to the origin of consciousness.

The remaining papers in the first volume deal chiefly with special cases in which Prof. Roux has elucidated the wonderful functional adaptation which is seen not only in the finest details of structure (such as the arrangement of the connective tissue in the tail-fin of the dolphin), but also in the makeshifts which the organism produces to make up for injuries to its original structure (as, for instance, the structure of the bone in the case of knee anchylosis).

The huge second volume is devoted to the subject of the "Mechanics of Development," of which study Prof. Roux may, as we have said before, be regarded as the founder. A considerable portion of the volume is taken up with replies to the successive publications of Driesch and Hertwig, who have pursued this branch of zoology with such brilliant success. Prof. Roux has only himself to thank if more attention is paid to the publications of these observers than to his work; for he has carried in this subject theorising and prolixity to an intolerable excess. The main difference between Driesch and Hertwig on the one hand, and Roux on the other, may be briefly stated: the former maintain that in the segmentation of the egg, we have a process which is essentially a mere multiplication of nuclei, all of which are similar to each other; the relative position of these nuclei determines what organs of the body they will eventually help to form; if their relative positions are altered by pressure or other mechanical means, their respective fates will be altered; or if one of the first eight segments of the egg be separated from all the rest, it is still able to form all the organs of the adult. Roux, on the other hand, maintains that by the formation of the first four segments of the frog's egg, the materials which are capable of differentiating themselves into the right and left sides and anterior and posterior halves of the animal are separated from each other, and that if one of the first two segments of the egg be severely injured, the other will develop into a half blastula, and eventually a half gastrula, and even further; the missing half will, however, be regenerated by the "reanimation" of the wounded blastomere by the migration of nuclei from the developed side.

It is of course extremely probable that in the normal course of development, the first segmentation furrow may coincide with the future long axis of the embryo, and if this is the case, the second furrow being at right angles to the first, will necessarily divide the egg into halves, one of which will be anterior and the other posterior. The question, however, whether this coincidence is essential or accidental, can only be settled by forcing the egg into such positions that the direction of the furrows dividing the segments is altered, and then observing whether the developmental history undergoes a corresponding alteration. Driesch and Hertwig have done this, and laid a strong foundation for their view, that the segmentation nuclei can be shaken together like a bag of balls, and still normal development ensue; and in the case of echinoderms and amphioxus, their theory, it seems to us, has been proved up to the hilt. Hertwig has written also a

paper on the development of the frog, in which he denies altogether the interpretations which Roux puts on his observations; he maintains that all which happens when one of the first two blastomeres of a frog is injured, is that the wounded side is delayed in its development. If the two segments are nearly separated from each other, each pursues its development as if it were a complete ovum. Roux's answers to these statements are two-fold: first he affirms that Hertwig, through not exercising continuous observation, missed the semigastrula stage, and only saw the embryo after the "post-generation" or "reanimation" of the wounded half had set in; and with respect to Driesch's work on echinoderm eggs, he suggests that by separating the segments or subjecting the egg to pressure, the normal machinery for bringing about the development is upset, and a special regenerative machinery, the reserve "idioplasson," brought into play; this occurs at a later period in the frog, but from the very beginning in the echinoderm.

It seems to us that with regard to the first point, Roux still holds the field; although we await with interest further observations on this subject from such a distinguished zoologist as Hertwig. It is *à priori* clear that in the ordinary course of affairs one blastomere gives rise to half the embryo; and as there are a large number of gradations conceivable between completely killing one blastomere, and only slightly checking its growth, there must be some point at which it is determined whether the remaining blastomere shall develop as a whole egg or in its normal manner. We cannot avoid the suspicion that Roux's semigastrulæ are conditioned by the contact of an actively developing half, with a stunned but not killed blastomere, whose influence is sufficient to prevent the other half acting as a whole egg. On the other hand, Roux's reply to Driesch seems to us extremely feeble. To assume that by slightly altering the conditions of a developing egg an entirely new machinery is brought into play, is not only an altogether unproved gratuitous hypothesis, but it is an attempt to discount any evidence which may be gathered from physiological experiments on eggs which behave differently to those of the frog. When the hypothesis of "mosaic development" or "self-differentiation" requires bolstering up in this fashion, it must be in a bad way.

The second volume contains a considerable number of papers, comprising the whole of Roux's work on the frog's egg. Besides the important and fundamental points we have mentioned, we find Roux's contribution to the vexed but still unsettled question of the nature of gastrulation, also some extremely interesting observations on the effect of alternating electric currents on the unsegmented and segmented egg. As the conclusion of the whole matter, Roux takes up a position decidedly opposed to the theory of epigenesis; he is in the main an evolutionist, though he admits that for the complete development of the organs from their embryonic rudiments the functional stimuli are necessary. Driesch has also proclaimed himself an evolutionist, though he points out (what Roux seems to us to forget) that in dealing with the facts of biology we must proceed inductively, and not set out with preconceived ideas as to the constitution of living matter.

E. W. M.

THE INDIAN CALENDAR.

The Indian Calendar, with Tables for the conversion of Hindu and Muhammadan into A.D. dates, and vice versâ. By Robert Sewell, late of her Majesty's Indian Civil Service, and Saukara Balkrishna Dikshit, Training College, Poona. With Tables of Eclipses visible in India, by Dr. Robert Schram, of Vienna. Pp. (including index) 169; tables, &c., cxxxvi. (London: Swan Sonnenschein and Co., Ltd, 1896.)

ALTHOUGH to many persons the chief interest of this publication (which must have cost the authors an amount of labour simply enormous) will be in an antiquarian and historical point of view, it has another aspect, judicial and practical, which was the immediate cause for its appearance. Documents bearing dates prior to those given in any existing almanac are often produced before Courts of Justice in India as evidence of title; and as forgeries, many of which are of great antiquity, exist in abundance, it is necessary to have at hand means for testing and verifying the authenticity of such documents when brought forward. Prof. Jacobi, Dr. Schram, and others, have within the last ten years thrown much light on the subject of the Indian methods of time-reckoning; but as their labours are only to be found scattered in scientific periodicals, the results are not readily accessible to officials and others to whom they are of importance in enabling them to determine questions in which the calendar, or rather calendars, observed in different parts and amongst the different peoples of that vast territory known as India, play an important part. Hence the Government of Madras requested Mr. Sewell to undertake the formation of a summary of the subject, accompanied by tables for ready reference. That gentleman not only accepted the task, but enlarged the scheme (which rendered it of a kind only to be called herculean) so as to make it include in its scope the whole of British India; and it has received the recognition of the Secretary of State for India. But besides containing a full explanation of the Indian chronological systems with the necessary tables for the conversion of their dates into ours, and *vice versa*, the volume is enriched by a set of tables of eclipses, most kindly furnished by that great authority on the subject, Dr. Robert Schram of Vienna. In the earlier stages of his undertaking, Mr. Sewell had the assistance of Dr. J. Burgess, late Director-General of the Archæological Survey of India. Afterwards he entered into correspondence with Mr. Saukara Balkrishna Dikshit, of the Training College at Poona, and it was agreed that the work should be completed under their joint authorship. The elaborate introductory treatise is mainly by Mr. Dikshit; several explanatory paragraphs, however, particularly those relating to astronomical phenomena, having been added by Mr. Sewell, who acknowledges the assistance received from Prof. Turner of Oxford, Prof. Kielhorn of Göttingen, and Prof. Jacobi. The tables of the latter were published in numbers of the *Indian Antiquary*, and Mr. Dikshit states that his calculations were, to a large extent, based upon these, though the original scheme had been propounded by M. Largeteau. We do not propose to enter into details here, which cannot be made interesting to the ordinary reader.

A great French astronomer once remarked that the only thing which made his head ache was the lunar theory; and scarcely less tiresome are calendar investigations. All honour, then, to those who do not shrink from these calculations. The last part of the work before us contains Dr. Schram's tables (formed by his own "Tafeln zur Berechnung der näheren Umstände der Sonnenfinsternisse" from the late Prof. Oppolzer's well-known "Canon") of the circumstances of all the eclipses visible in India and its immediate neighbourhood from A.D. 300 to 1900. It had been intended that these should be accompanied by maps, showing the centre-lines, across the continent of India, of the phenomena in question; but it was not found possible to complete these in time, owing to the numerous calculations that had to be made in order that the path of the shadow might be exactly marked in each case. Dr. Schram hopes, however, to be able soon to publish the maps separately, as they will form a very useful guide to the tables.

The different eras adopted in Hindu chronology form a somewhat troublesome subject. Those of Vicramaditya and Salivahana are largely used in the northern and southern provinces of India respectively, the former commencing in B.C. 57, the latter in A.D. 78 of our reckoning. But in Bengal, and some other parts, eras are used, the epochs of which seem to have been derived from that of the Hegira, or, as our authors prefer to spell it, Hijra; but by preserving solar time and the sidereal year preferred by the Hindus, the dates of these differ from those actually employed in the Muhammadan calendar. This is, however, of course itself now one of those used in many parts of India since the Muhammadan conquest, and is therefore included in the work before us. It is, as is universally known, reckoned from the flight of Muhammad from Mecca to Medina, which took place, by our chronology, on July 15, A.D. 622. In principle it is essentially lunar, the year being made to consist of twelve lunar months, or about 354 days; by the use of common and intercalary years (nineteen of the former and eleven of the latter in a cycle of thirty years), the length of a year is, in fact, maintained at 354·367 days. As this is 10·875 days short of a true tropical year, the Muhammadan year retrogrades through all the seasons in about thirty-three years. Had its length been the same as that of ours, the year of the Hegira would now be 1274, whereas their year 1314 commenced on June 12 in the present year (1896). We must demur to one statement (p. 40, note) of our authors: that in Christian chronology it is somewhat uncertain whether the years are current or expired. No doubt those who have not studied the matter are sometimes confused in the backward and forward reckoning by there being no year 0, which is neither B.C. nor A.D. But there is no uncertainty as to what is really meant. The years are reckoned from Christ's birth, supposed originally (but erroneously) to have taken place at or near the end of B.C. 1. At the end of A.D. 1, therefore, one year had expired, and at the end of 1895 that number of years. Ordinary people are sometimes puzzled by the simple question when a given century ends, but there is no real doubt or uncertainty in the matter; the present century will end at the end of December 31, 1900, and the twentieth will commence on January 1, 1901.

W. T. LYNN.

DOMESTICATED ANIMALS.

Domesticated Animals: their Relation to Man and to his Advancement in Civilisation. By Nathaniel Southgate Shaler, Dean of the Lawrence Scientific School of Harvard University. Pp. 264. Illustrated. (London: Smith, Elder, and Co., 1896.)

THOUGH the literature upon domesticated animals is of immense extent, we are unable to call to mind any work in which the subject is approached from quite the same general standpoint as in this suggestive book of Prof. Shaler's. The greater part of the volume consists of a series of essays on the dog, horse, poultry, &c., and even insects, so far as any insects can be said to be domesticated, reprinted with some amplifications from *Scribner's Magazine*, and written in a far more philosophical manner than is customary on such a subject. The leading idea, the connection between the practice of domesticating animals and social evolution, has of course not been neglected by sociologists; but it is discussed, together with the causes which have led to the selection of forms for domestication, and their consequent mental and physical modifications, in a manner well suited to attract the general reader who is a lover of animals, and to give an idea of the important part which their domestication has played in human progress. It is for him, rather than the man of science, that the work is intended; it is not detailed in treatment, and is in part covered by the writings of Darwin and Romanes. A good example of Prof. Shaler's method is afforded by the line of argument in which he points out that the invention of the horse-shoe made possible the disciplined use of the horse in Western Europe, and its differentiation into breeds. This led to the development of the war-horse, which played an important part in the warfare between Christian and Mohammedan States, as at the Battle of Tours, and promoted the institution of organised armies, and consequently of centralised States. Referring to the necessity of horses in military operations, he makes the curious deduction that China is unlikely ever to become a menace to outlying countries, because she cannot, and may never be able to, provide the horses necessary for the use of invading armies.

There is no mention in the book of the reindeer, surely a very important factor in the economy of the races which use it. On the vexed question of the origin of the dog, it is noteworthy that the author does not recognise it as the descendant of any surviving wild form.

The closing chapters on "The Rights of Animals" and "The Problem of Domestication" are published for the first time. In the former, the author, a strong and genuine sympathiser with animals, defends the practice of vivisection within proper limits. "So far from natural science tending in any way towards cruelty, it has been the very guide in the development of the modern affection for living beings. By showing something of the marvels of their structure and history, it has increased in a way no other influence has ever done the conception which we form as to their dignity and the wonderful nature of their history"; a point both true, and usually disregarded. Like every naturalist, Prof. Shaler deplores the rapidly advancing extermination of animal types.

particularly among the larger kinds, and offers various suggestions, both as to increasing the number of domesticated forms and the conservation of wild species in reservation-areas, such as the Yellowstone Park. Valuable as many of his proposals are, it is to be feared, in the present relation of natural science to bodies politic, that they are somewhat of an utopian character. It is not easy to maintain such areas under entirely natural conditions and free from interference, administrative or otherwise. To take a small instance: it is notorious that in the New Forest, perhaps our nearest approach to such an area, the insect-population has greatly diminished during the last thirty years, and many rare and retired species are on the point of extinction.

In the artistic, though somewhat unequal, illustrations, and the excellence of printing and paper, the book is worthy of high praise. W. F. H. B.

OUR BOOK SHELF.

A Geological Sketch Map of Africa South of the Zambesi. By E. P. T. Struben, F.R.G.S. (London: Edward Stanford, 1896.)

THE chief object of this new map, and accompanying pamphlet, of South Africa is to show that the Witwatersrand beds occur over a large portion of Africa south of the Zambesi. The band of dolomite, already described by Mr. Draper, is used by the author as a means of identifying the various scattered portions of sandstones, conglomerates, &c., occurring in South Africa, and which in many localities have proved to be auriferous. That the auriferous strata of the Rand occur outside the Transvaal is an established fact; but Mr. Struben hardly brings forward enough evidence to show that the sandstones, conglomerates and dolomites, recognised by him as identical with the Witwatersrand beds, are really all of one age.

The table of strata is very meagre in detail; the formations recognised being "Granite, Carboniferous beds, Sandstones, Shales and other stratified rocks, and Limestone." The formations are too much lumped together to be of much service, and there remains a doubt that the dolomite limestone mentioned by Mr. Struben is of various ages. A strip of crystalline limestone is represented near the coast north of the Umzimkulu River, and coloured similarly to the dolomite, but no mention is made of the cretaceous rocks of the east coast. There is no attempt made to show the relationship of the Rand beds to the Dwyka conglomerate, the Zwaartebergen quartzites, and the older rocks of the Cape. The metamorphic schists underlying the formations of South Africa are not mentioned. The relation of the Rand beds to the coal-bearing strata is also not clearly stated. In Natal the relationship is drawn as one of perfect conformity; but it is certain that in the Transvaal the coal-bearing rocks are unconformable to the Rand beds, and of much more recent date.

Mr. Struben's map, as showing the localities in which the minerals occur in South Africa, is valuable, but it does not approach in scientific value to Dunn's map of South Africa. The stratigraphy of South Africa is extremely complex, and a solution can only be arrived at by a survey, such as was commenced by Dunn, Griesbach and Stow.

Wayside and Woodland Blossoms. A Pocket Guide to British Wild Flowers for the Country Rambler. (Second Series.) By Edward Step, F.L.S. Pp. 170. (London: Frederick Warne and Co., 1896.)

WE are glad to know that the first volume published under the same title as this has met with the success it deserves, and we hope the present pocket-book will have a similar welcome extended to it. Four hundred species of flowering plants were described and illustrated in the first series, which Mr. Step now supplements with descriptions of 325 species, 130 being represented upon coloured plates, while 23 are shown in black and white. The plates render the identification of a plant a comparatively easy matter, and the clear descriptions of the plants are worthy accompaniments to them. Mr. Thiselton-Dyer should rejoice at the opportunity which the book affords every one to learn something about botany from "wayside and woodland." It will be remembered that as president of the botanical section of the British Association last year, he condemned the system of botanical teaching followed in many schools for examination purposes, and pleaded that the subject should be developed as an educational instrument. In the course of his address he said: "The modern university student of botany puts his elders to blush by his minute knowledge of some small point in vegetable histology. But he can tell you little of the contents of a country hedgerow; and if you put an unfamiliar plant in his hands, he is pretty much at a loss how to set about recognising its affinities." Mr. Step's book provides such students with the materials to make up their deficiencies; it is a book which will develop the observant faculties in young students of natural history, and one which will make more lovers of botany than all the examination syllabuses and text-book formulas yet devised.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Fine Shooting-Star; and Heights of Meteors in August and November 1895.

A REMARKABLY bright shooting-star was seen here on Saturday, June 13, at 10.59 p.m., under such favourable conditions of a clear sky and warm calm air on that evening, that it may possibly have happened that other notes were kept of its appearance, in the South of England, by astronomical observers. It was not a large-sized fireball, but in its course of about 30° it increased quickly from the brightness of a 1st mag. star to that of Sirius and of Jupiter, and just before its disappearance it shone with a short white flash as bright as Venus, which lit up the sky quite distinctly to about 20° or 30° from its final bright expansion. The head was white, free from sparks, and left along the greater portion of its course a yellow streak of light, of which a portion 8° or 10° in length was visible 10 seconds, while a shorter piece, 3° or 4° long at the end of that, where the bright flash occurred, growing white and misty by degrees, remained visible for 40 seconds. Duration of the flight about 2 seconds; from 230°, + 20° to 208°, − 4°; the patch of long-enduring streak extending about from 212°, ± 0°, to 209°, − 3°.

This track is directed from the head of *Andromeda;* and albeit the meteor greatly resembled a bright August Perseïd in appearance, of which shower first members have been traced as early as the beginning of July, proceeding from radiant-points in much lower R.A. than the chief centre of the system, yet the displacements of this meteor's course in time and in position from the main stream of the Perseïds are too considerable to allow an explanation of its appearance of that kind to be proposed as a probable conjecture. But there are no less than four ordinary radiant points, all active at this time, as Mr. Denning has informed me, in *Cygnus*, *Lacerta*, and *Honores Frederici*, in the "List of 918 Radiant-points" which he has published in the Astronomical Society's *Monthly Notices* (vol. 50, p. 410, May 1890), at distances back along the line of flight, of 55°, 70°, 80°, and 100°, from which its flight was directed accurately; and it is from the last of these slender meteor-sources (No. 174 in his List), at 354°, + 39°, about 5° south of ι, κ *Honorum*, a centre of swift, long-pathed, streak-leaving meteors in June and

July, with a fine Venus-like shooting-star just similar to this present meteor (its streak remaining visible 5 secs.), observed at Bristol on June 14, 1887, among them, that Mr. Denning considers it most probable that the real course of this bright meteor was directed. Its path and that of the just similar one observed at Bristol, prolonged backwards, intersect each other at 354°. + 36°, close to this well-marked shower-position; and if additional notes of the meteor have been obtained at other stations, it will be an interesting question to examine if they bear out this conclusion.

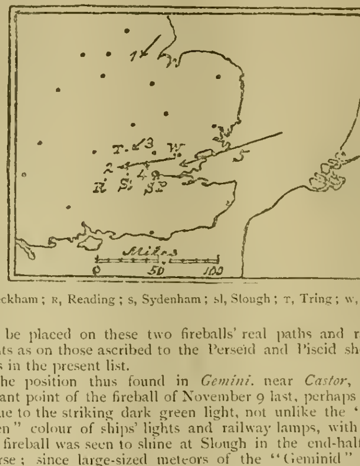
I take this opportunity of the returning abundance of meteors of the August period to beg to correct some errors of calculation and projection in my letter on "Heights of August Meteors" in NATURE of September 5, last year (vol. lii. p. 437), which gave confused descriptions, without, however, tripping (except slightly in the case of the second meteor) in the real values of the heights there found, of two meteors doubly observed at Tring and at Slough on August 11, 1895. The places over which the meteors were vertical when first seen, and at disappearance, were laid down in proper relation to Tring and Slough on a map of England, but from left to right instead of from right to left of the Tring and Slough meridian; so that although both their radiant-points were really easterly, their paths were described as from Oxfordshire to Middlesex, and from west to east across the northern part of Buckinghamshire, in my letter. The corrections applied to the observed paths of the second meteor were somewhat incorrectly chosen, and gave thereby resulting heights and a length of path which were somewhat faultily arrived at; while the radiant-point of this meteor (α Persei), given by the observations directly was a little departed from, and its altitude and azimuth were also given as 45°, 34° north of east, instead of 35°, 44° north of east. As uncertainties from errors inherent in meteor-observations (rarely very small ones) are unavoidable in comparing them together, a recalculation of both paths will, it seems probable, serve better to correct this maze of errors and mistakes, than to try to rectify individually the above principal ones, and a few lesser faults which the paths deduced last year contained.

Two other accordances, of a Perseid shooting-star between Tring and Slough, and of a small fireball between Tring and Sydenham, in August last, and one of a rather notable fireball in November last, have afforded, since the path-descriptions in my former letter, some fairly good materials for height-determinations, although the data of the two fireballs' paths are of a little looser kind than those of the two foregoing and the one now newly-added shooting-stars. In the accompanying table I have grouped together what appear to be the real courses (including the two shooting stars' recalculated paths as Nos. 2, and 3, in the table), of all the meteors found here to have furnished accordant observations in last August and November; and I may add, in gladly expressed acknowledgment of the aid supplied abundantly by accuracy of the original observations to the general certainty of these determinations, that nearly all the present list of meteor-heights (only excepting those of the fireball of November 9) is due to some weeks' actively continued watch, with careful records of descriptions and well-mapped courses by the stars, successfully maintained at Writtle and at Tring by Mr. J. A. Hardcastle in order to obtain them, on the Perseids and occasional meteor-members of other showers more or less conspicuous during the period of the display from Perseus, in August last.

In cases of loose, and of partially inconsistent descriptions, much latitude of choice is left to adjust the observed tracks to each other; but the limits of this choice become, in general, narrowly restricted if the ordinary descriptions and characters of meteor-flights are kept in view, and if any wholly improbable results, as of rising upwards, or of paths abnormally at variance with the usual heights, and not reconcilable with the acknowledged astronomical velocities of meteors, are rejected. The course of the fireball No. 5, of November 9, descending almost vertically in E.N.E. at each of the stations, Peckham, Slough, and Reading, where it was observed, along nearly the same apparent path (but beginning at those stations at nearly equal, and ending at very unequal altitudes), was situated so unfavourably for determining its radiant-point by the observed paths' mutual intersections, that only the ordinary conditions of meteor flights (attained to here by trial and error combinations of more and more appropriate paths to satisfy them and the tolerably accordant observations also) could be usefully resorted to as the sufficient additional criterion needed to define the radiant-point, or the line of real direction of the meteor's course.

The observed paths at Writtle and at Slough of the Perseid shooting-star, No. 1, are also in the unfavourable position of nearly "fore-and-aft" conjunction, but deviate sufficiently from it to yield the radiant-point noted in the list, by their mutual intersection, and from the heights, and meteor-speed given in the list, which are computed from it, this position of the point appears to stand in no further need of very material amendment by the proof test of the atmospheric and astronomical criterion.

In the case of the small fireball No. 4 (if the same meteor, as assumed from their resemblance, was really referred to in both the observations), besides a pretty large divergence from parallax direction between the two path-positions, making a rather considerable reconstruction of them both essential, a nearly lengthwise conjunction (as in Nos. 1, and 5) also once more occurs, introducing a large uncertainty, scarcely less than in the case of the fireball No. 5, into the position of the radiant-point, and into the consequent heights and length of path computed from it; which could only be overcome, as is done, it is to be hoped successfully, by the same tentative method of proceeding as that which was used to fix the real path and radiant of that latter fireball. With heights not far removed from sixty miles, and speeds not far from parabolic ones admitted, the construction's freedom becomes so greatly narrowed in these two fireballs' otherwise most equivocal-looking cases, that nearly as great, though (by unadjustable differences in the observations) still questionable dependence



P, Peckham; R, Reading; S, Sydenham; SL, Slough; T, Tring; W, Writtle.

may be placed on these two fireballs' real paths and radiant-points as on those ascribed to the Perseid and Piscid shooting-stars in the present list.

The position thus found in *Gemini*, near *Castor*, of the radiant point of the fireball of November 9 last, perhaps affords a clue to the striking dark green light, not unlike the "signal green" colour of ships' lights and railway lamps, with which the fireball was seen to shine at Slough in the end-half of its course; since large-sized meteors of the "Geminid" shower diverging between the end of November and the middle of December from the immediate neighbourhood of the fireball's radiant-point position so determined, are notable for frequent occurrence of green hue in their nuclei. The low height of eight miles assigned to the meteor at its disappearance would nearly break record[1] of a fireball's deep penetration towards the earth before extinction, if the extraordinarily bright detonating fireball of December 14, 1890, had not been shown undoubtedly to have ended its shining course at not more than seven or eight miles above the earth, and that, too, by a curious coincidence, like the present meteor's end-point, over Billericay or some place close to Billericay, in Essex! Should observers in that latter county, or in any of the adjacent East Coast districts, have noted particulars of its appearance on November 9, which happened on a clear night during a prolonged display of a widely-observed and rather fine aurora (and, though the memory is a sad one to recall, especially on a date which was an annual one of rejoicing

[1] The fireball which accompanied the fall of aërolites at Weston, Connecticut, in the United States, on December 14, 1807, was found by Dr. Bowditch to have remained luminous in its descent until only about three or four miles above the places on the earth's surface where the aërolites were scattered.

Table of observed Paths and Real Heights and Radiant Points of Meteors doubly observed in August and November 1895.

in England and for the metropolis, only a few minutes before the occurrence of the terrible railway accident at Grantham on that night), I would be glad to know if they confirm the near approach to earth over the Brentwood Hills (as the end-point), and the position near Castor (as nearly the point of first appearance), assigned by this discussion to the meteor's flight; or if, as seen much sideways from its plane of fall, in counties north of Essex, the meteor's apparent line of flight may have been but little accordant perhaps, or even, quite possibly, not at all conformable with these sky-positions?

With regard to Mr. Denning's identification of the course of the above described bright meteor of the 13th inst., with a radiant-centre near *Honores*, I may mention in concluding that on the 19th inst., at 11.56, I noticed here a long-pathed streak leaving, 2nd mag. meteor shoot swiftly (about 30° in $1\frac{1}{4}$ sec.) from 195°, + 68°, in *Draco*, to 181°, + 39°, in *Canes Venatici*, leaving a thin white streak for $2\frac{1}{2}$ seconds along its whole track. This course prolonged backwards about 60° proceeds from 350°, + 37°, only 3° or 4° from the place at 354°, + 39°, of the radiant No. 174 of Mr. Denning's list; and like the brighter shooting-star of June 13, it evidently belonged to this same June "Honorid" system. Mr. Denning's outline of the shower's duration, through the latter half of June and the first week of July, with a date of maximum on June 26, would thus seem, for this year's return of its meteor-period at least, to be in a fair way to be realised. A. S. HERSCHEL.

Observatory House, Slough, June 20.

Purification of Sulphur.

IT is never a very pleasant or gracious task to reply to criticism. When that criticism, however, is based on a misapprehension of the facts, and is consequently wrong and misleading, and is, moreover, enforced by whatever weight "authority" may carry, its correction is simplified down to a plain matter of duty. The criticism to which I refer is contained in Prof. Armstrong's address to the Chemical Society (*Chem. Soc. Journ.*, vol. xxxix. p. 1160), which has just come before me.

The passage to which I refer runs as follows. "To return to sulphur, an abstract account has recently been published in the *Proceedings* of the Royal Society (1894, lvi. 32) of observations by Threlfall, Brearley and Allen, on the electrical properties of pure (*sic*) sulphur, *i.e.* sulphur from the Chance recovery process purified by distillation and exhaustion in vacuo. Such a process cannot be accepted by any means as an exhaustive one, and it appears almost to be a case of 'love's labour lost' to apply to such material the infinite care which the authors appear to have taken in making the electrical measurements. Yet they arrive at the important conclusion that so long as a single modification be dealt with, such sulphur does not conduct while solid. A mixture of two modifications, however, does; but in view of the possibility of changes taking place during the production of the mixture, of conducting impurities being introduced or generated, it is difficult to regard this latter conclusion as established; the more so as the authors in question have found that, as the temperature was raised the conductivity of the sulphur increased slightly up to the melting point, when there was an enormous increase."

Prof. Armstrong prefaced the paragraph which I have quoted above, by some rather ungenerous remarks as to the supposed attitude of physicists towards the question of chemical purification of material. It is now eight years since I began to endeavour to purify materials, so that I can, at all events, agree with Prof. Armstrong on one point, viz. that it is much more difficult to purify a substance up to the furthest limit of chemical discrimination, than it is to determine its physical properties afterwards. In the passage to which I now allude —and which I do not intend to quote, for I feel sure that Prof. Armstrong will, on consideration, agree with me that it is better forgotten—the "tongue of the scorner" is thrust out at those physicists who take no thought as to the condition of material examined by them. However true this may once have been, I am sure that nowadays it is a mere superstition to suppose that physicists, as a body, are callous on the subject of purification. A great deal of modern work in this domain of chemistry has been done by professed physicists; and indeed, though I have myself known several physicists enormously interested in questions of purification, I have only known one chemist whose life-long endeavour was to get things pure, and that was the late Prof. Josiah P. Cook, of Harvard. Passing to the immediate point, Prof. Armstrong objects to the use of the word "pure," made by myself and my co-workers. With regard to this, I may say that Prof. Armstrong labours under the disadvantage of only having an abstract under his notice. In the paper (if it ever gets published) he will find that this very matter is discussed at, perhaps, too great a length, and the conclusion arrived at that the word "pure" ought to be kept for substances in such a degree of purity that existing chemical or physical means fail in discovering any foreign substance. "Pure," therefore, as we have used the word, has no meaning except in connection with the existing state of the art of chemistry, and was adopted by us rather than the word "purified," as the result of some consideration, in which a desire to avoid pedantry had some weight. Since Prof. Armstrong refers eulogistically to Stas—as who would not—I may perhaps refer him to the following passages by Stas himself (*Bulletin de l'Académie Royale des Sciences, &c., de Belgique*. 2 séries, vol. x. p. 253), than whom no one could be more careful as to the use he makes of the word "pure."

"Jusqu'ici, il n'y a que M. Dumas qui ait tenté de faire la synthése du sulfuré d'argent. Pour déterminer le rapport proportionnel de ses éléments, il a sulfuré directement l'argent par *du soufre pur* qu'il faisait passer en excès." . . . "En suivant cette méthode, j'ai fait deux séries d'expériences: la première, comprenant trois synthèses par *du soufre pur* amené en excès." Stas gives no details as to the preparation of his "soufre pur" (which he would certainly have done had elaborate precautions been taken); and as a matter of fact, Stas' sulphur was probably far less pure than mine, for in those days there was no "Chance" sulphur. So much for the word "pure."

Prof. Armstrong considers that the process of purification employed by us is "by no means an exhaustive one," &c. A process is, we take it, exhaustive when it exhausts the resources of physics, including chemistry. Now, we spent four years in trying all likely and many unlikely methods of purification. We finally, by sheer good fortune, received some Chance sulphur, and our methods of discrimination at once revealed to us that, when dust and water were removed, it was purer than any we had been able to prepare hitherto by the most elaborate means; and we adopted it as our source of sulphur in consequence of this discovery. On the other hand, there are doubtless degrees in the purity attained by the commercial product. The first lot we received (a present from Mr. Chance) was much purer than some afterwards purchased; and with this later sample the process we employed for purification would probably not have been sufficient.

With regard to the question of the adequacy of the purification—for this is the important point—we arrived at a stage at which no chemical means enabled us to detect any impurity whatever, and the specific resistance (if one may so misuse the term for a body which does not obey Ohm's law) rose above 10^{28} C.G.S. units; our limit of discrimination, and probably the furthest hitherto *certainly* attained.

As we had found that the purer the sulphur the better it insulated, as with this sulphur we could absolutely find no impurity at all, and as all our means of purification (except by repetition) were exhausted, we felt that we had done all that could possibly be done.

The conclusion at which we arrived—viz. that so-called mixtures of crystalline and amorphous sulphur conduct, whereas pure crystalline sulphur does not—seems to us to be of considerable importance, and we therefore spared no pains to assure ourselves of its truth. For this purpose we prepared crystalline sulphur films, ascertained their property by non-conductivity, and then converted them into the conducting mixture by appropriate heating and cooling. Conversely, we caused conducting "mixtures" to become non-conducting by annealing. Prof. Armstrong's criticism, therefore, is wrong, and the uncertainty, which he assumes, does not exist. It is as certain that crystalline sulphur is at least about a million times more non-conducting than "mixed" sulphur, as that copper conducts better than glass. We spent some years in assuring ourselves of the truth of this proposition, and we feel that we should be shirking our philosophical duty were we to allow this conclusion, so laboriously reached, to be set aside, or rendered nugatory, by a criticism based on a misapprehension, and enforced by all the weight which Prof. Armstrong's utterances so rightly carry.

I confess I am unable to reply to that part of Prof. Armstrong's criticism in which the above conclusion is supposed to

be in some way dependent on the fact that any variety of sulphur increases in conductivity with rise of temperature. Unless it is suggested that we did not know one temperature from another, I fail to understand this criticism. RICHARD THRELFALL.

University, Sydney, N.S.W.

I SEE no reason to recall what I have said regarding the general attitude of chemists and physicists on the question of the influence of minute traces of impurity; and when I come across the remark in Messrs. Threlfall, Brearley and Allen's paper in the *Phil. Trans.*, that "it is not too much to say that the electrical action of most bodies in a pure state is entirely unknown at present," I feel there is not much difference of opinion between us.

Then, as to my being guilty of that unpardonable crime—pedantry—it has always seemed to me that those of us who undertake scientific work should also strive to be scientific, *i.e.* exact, in their use of language. Those who had the great good fortune to be present a year or so ago at the NATURE dinner, and to hear Huxley's marvellous speech—almost, if not the last he delivered—will recollect how strongly he insisted on the importance of greater care being taken in the writing of papers describing scientific inquiries. In a conversation I had with him afterwards, he greatly lamented the careless manner in which such work was too frequently done.

Now if *pure* mean "free from mixture," a pure substance must, as I have said, ever remain an ideal conception; the purist must ever regard all things as impure. Prof. Threlfall tells us that "the word pure has no significance except with respect to a definite state of the art of chemistry." I would rather accept the meaning which is to be found in the dictionary, *pace* Stas even; and would prefer to assert that the word too frequently has no significance except with reference to an indefinite state of the mind of the person—chemist or physicist—using it. To my mind, there can only be degrees of impurity—not of purity.

Whatever time Prof. Threlfall and his colleagues may have spent in seeking to purify sulphur, the fact remains that their experiments were made with sulphur which they obtained by chance, and that the only method of purifying it they adopted was to distil it several times in vacuo, after filtering it while molten through glass wool and platinum gauze, and then to fuse it in vacuo—in order, they tell us, to get rid of gases (probably water vapour, they say) given off even from the purest samples. But distillation in vacuo, even when followed by fusion in vacuo, can scarcely be regarded as a process which "exhausts the resources of physics, including chemistry."

"Chance" sulphur is prepared by burning sulphuretted hydrogen. It is probably impossible to burn sulphur without producing some sulphuric acid. Messrs. Threlfall, Brearley and Allen, however, do not even refer to the possibility of its presence, and apparently took no precaution whatever to eliminate it, if present.

They tell us that on breaking up such sulphur after it had been strained while molten through glass wool and platinum gauze, it emitted a horrible smell of gas-lime, "which shows that it requires to be distilled if sure results are to be obtained." I imagine, therefore, that the sulphur they used initially was by no means so remarkably "pure"; as they also state that gases were given off even from the purest samples when fused in vacuo after distillation, it may well be doubted whether so simple a process as mere fusion could suffice to effect the necessary final purification.

Prof. Threlfall's statement that conducting "mixtures" were caused to become non-conducting by annealing, is apparently a good answer to my criticism; but by no means finally disposes of it. The structure of the two materials may have been very different, and such in the one case as to allow an impurity to act, which in the other case might be inoperative. By my reference to the conductivity of sulphur at temperatures above its melting point, I meant to imply that the behaviour described afforded indication of the presence of impurity; for I do not believe that even molten sulphur is a conductor. Of course, at present, this is but an opinion, but it may not be inappropriate to direct attention to the recent most remarkable observations of Dewar and Fleming on bismuth, showing that an amount of impurity altogether beyond detection by chemical means may entirely alter electrical properties.

I still, therefore, regretfully retain my opinion, and fear that, notwithstanding the great care lavished on the work of Prof. Threlfall and his colleagues, it will be necessary to repeat it, perhaps over and over again—a possibility which they apparently themselves foresee in the introduction to their paper—before so remarkable a conclusion as that they have arrived at can be regarded as established.

H. E. ARMSTRONG.

Increasing the Efficiency of Röntgen Ray Tubes.

MR. J. C. PORTER, in a letter in NATURE of June 18, describes a method of increasing the efficiency of a Crookes' tube. I have for some weeks used another very simple method to obtain the same result. This consists in placing the flame of a small glass spirit-lamp in the angle formed by the Crookes' tube and the wire passing to the kathode, and allowing a series of small sparks to pass to the flame from the wire.

Burnley, June 29. T. G. CRUMP.

THE POSITION OF SCIENCE AT OXFORD.

WHILST the study of natural science has been progressing rapidly in other universities and colleges during the last ten or fifteen years, it is a matter of common knowledge that it has progressed very slowly indeed in the University of Oxford. It would be incorrect to say that it has not progressed, for there has been during the last few years a steady, though very gradual, increase in the numbers of men reading for honours in the final school of natural science. In 1885 twenty-two men obtained honours in sciencce, in 1895 there were forty-three names in the class list, and a rather larger number in 1894. The school has just doubled itself in ten years, but for all that the numbers are still small, and out of all proportion to the provision that has long existed for science teaching in the University. It must be understood at the outset that the University, considered as a body separate from the colleges which compose it, has not dealt ungenerously with science. The staff of professors, and the emoluments attached to their chairs, compare favourably with those of any other university in Great Britain; and Oxford actually set the example, at great cost to itself, of building a museum and equipping laboratories for educational purposes. Moreover, the opportunities of scientific study in Oxford are greatly enhanced by the existence within the precincts of the museum of a first-rate scientific library, such as is not possessed by any other college or university in the kingdom. It is a strange thing that when it has so many advantages, Oxford has allowed itself to be completely outstripped in this particular path of intellectual progress.

It is the purpose of the present article to discuss the possible causes of comparative failure of the science school at Oxford. A complete failure it is not, for, however poor its numerical results may be, it has long been recognised that the attainments of the limited number of scientific men which it turns out compare well with those of men who have been educated in other places.

It is commonly supposed that the prime cause of the insignificant numerical result is the small encouragement given to scientific study in the shape of fellowships and scholarships; and those who hold this opinion believe that if the colleges were to do what is conceived to be their duty in this respect, the science school would progress by leaps and bounds.

With respect to scholarships and exhibitions, it is apparent, from an analysis of the figures, that science does not get what may rightly be held to be its due. The *University Calendar* for 1896 shows that there are in Oxford some 500 scholarships of an annual value of £80 a-piece, and in addition some 225 exhibitions, the annual value of each of which may be placed at £40, These figures apply only to college scholarships and exhibitions, and so it appears that the colleges, apart

from the University, exercise an intellectual patronage to the extent of nearly £50,000 per annum. How is this patronage exercised, and what share of it falls to natural science?

It is not unreasonable to say that bare justice would be done if the number of scholarships allotted to science bore the same proportion to the number of men reading for honours in that subject as the number of scholarships allotted to literary subjects bears to the number of men reading for the literary schools. This bare measure of justice is not done. In 1895 one hundred and fifty-three men were classed in the honour school of Literæ Humaniores (a number beyond all previous precedent); eighty-seven were classed in Modern History; sixty-six in the honour school of Jurisprudence; forty-three in Natural Science; thirty-seven in Theology; twenty-three in Mathematics; and one in "Literis Semiticis"; in all four hundred and ten. Deduct twenty from this number to exclude those who took a second final school, and there remain three hundred and ninety, of whom forty-three, or one ninth of the whole, belonged to the school of Natural Science. Science, on this reckoning, should claim fifty-five out of the five hundred existing scholarships. It is not very easy to ascertain the exact number of science scholarships, but there are certainly not more than forty. It appears from the *University Gazette* that in the academical year 1894-95 only ten out of twenty-one colleges offered scholarships or exhibitions in Natural Science, and that those ten have offered science scholarships for some years past. The ten are Balliol, Merton, New College, Magdalen, Christ Church, Trinity, Corpus Christi, Jesus, Keble, and Queen's. The scholarship at the last named, though in fact awarded to a candidate who offered Natural Science, was equally open to candidates offering Classics or Mathematics. In addition, St. John's offered and awarded a scholarship in mathematics and physics, either separately or in combination. As each of the ten colleges gave one science scholarship, and as the tenure of a scholarship is four years, it follows that there are only forty science scholarships in the University, or if St. John's be added, forty four—at the lowest computation ten less than there should be.

The paucity of science scholarships has been a frequent subject of comment; but the colleges have a ready and a very plausible answer, which is best illustrated by the fact that in November last Balliol did not award a science scholarship because no candidate of sufficient merit presented himself. It is a fact that the candidates for science scholarships are not only few in number, but also of low average merit; there are, of course, brilliant exceptions. It is not easy to fix a common measure for the intellectual acquirements of classical and scientific students, but as far as a comparison can be instituted, it is vastly to the advantage of the classical scholar. He is a better classic than his scientific confrère is a man of science, and is in addition more widely read and has a greater knowledge of subjects of general interest. The most that can be said is that the science scholar knows a little of classics, a classical scholar as a rule is profoundly ignorant of science. But in powers of expression, in the ability to handle an unfamiliar theme, and in range and variety of knowledge, there is simply no comparison. Hence the colleges justify themselves by saying that they award scholarships to candidates of the greatest intellectual merit, and it is their experience that the greatest merit is found in those who have had a classical education. As for science scholarships, the competitors, they say, are not worthy of the prize, and the prize is accordingly withdrawn, with the result that the number of science scholarships tends to diminish rather than to increase.

This is true, and it is a lamentable state of things, pointing to a serious deficiency in the secondary education which precedes and leads up to a University education. It is, however, remarkable that Cambridge, which gives plenty of science scholarships, finds no difficulty in getting candidates of sufficient merit. The explanation of this is probably somewhat as follows. At Oxford scholarships are nearly exclusively awarded to boys who are still at school; very few are open to undergraduates who have been in residence for more than one University Term. At Cambridge many scholarships are open to men of one year's standing, giving an opportunity to those who have come up to the University with a fair general education and only a moderate acquaintance with science, to learn enough science in their first year to bring themselves up to the standard of a scholarship; many at Oxford would be glad of such a chance, but it is not open to them. In the second place, the science school at Cambridge has acquired such a prestige that the best boys go there, and only the second best to Oxford; and thirdly, Oxford draws its undergraduates more exclusively from the great public schools than Cambridge does. Taken on the whole the teaching of science in public schools is bad. There are, of course, some exceptions, but they are rare, and in many science can hardly be said to be taught at all. It may be objected that every public school has one or more science masters of tried capacity, and that science is a compulsory subject in nearly all. It may be so, but the inducements offered to the study of science in public schools are very few; in most of them there are not only no inducements, but the study is openly discouraged. Boys are not generally inclined to give themselves unnecessary trouble over their studies, and are only too ready to neglect that which may safely be neglected; the science masters have no chance with the majority of them, and have to resign themselves to giving as much trouble and time as school regulations permit to the few enthusiasts who care to add science to their classical burdens. For all the pretence that public schools make of teaching science, the average schoolboy comes up to the University destitute of the most rudimentary scientific ideas. If, as is sometimes the case, he wishes to take up science on his arrival there, he has to begin with ideas and facts which he might well have learnt in the nursery; if he prefers a literary course, he remains to the end of his life as ignorant of the alphabet of science as any baby. There is room for considerable difference of opinion as to how far the technicalities of any branch of science should be taught to schoolboys, but it must be admitted that in this age, which is above all things an age of science, an understanding of the fundamental laws of at least physics and chemistry ought to form a part of that vague but cherished ideal "a good general education." But are the public schools altogether to blame? In our system of education the universities call the tune, and the schools may be excused if they only play what is called for. The universities do not call for science. They say in effect, "before you can be of us you must know Latin and Greek, and you must know a certain minimum of arithmetic and of algebra or of geometry, but of any knowledge of science you may be as innocent as a babe. We care nothing for it, and we will confer our highest distinctions on you without asking you for one syllable of it."

The gates to an Oxford career are the University examination, responsions, or more familiarly "smalls," which takes no cognisance of science, and the college matriculation examinations, which in only a few cases give it a bare recognition. So long as this is the case, science will not be seriously taught at the public schools, and there will be a dearth of adequate candidates for science scholarships. The justification of the colleges amounts simply to this—that by their system they have discountenanced the teaching of science in schools, so that the schools cannot send them candidates fit to hold

science scholarships, and therefore the scholarships are not awarded.

Oxford fosters the exclusive study of classics in the public schools, and it also does its best to shut its gates against those who have received what is called a modern education in other schools. The burden of matriculation and responsions is not a very heavy one to a fair classic, but it is sufficient to keep out many who have had an exclusively classical education, and is quite prohibitive to most "modern" boys. They go either to Cambridge, where the burden, especially as regards matriculation, is much lighter, or to one of the newer universities. In intention Oxford is possibly right. The product of a modern education is often wofully illiterate. He has the credit of knowing an extensive range of facts, and of having clear ideas about a large number of phenomena ; but he is often incapable of stating his facts in plain English, and is so deficient in expression and in the power of arrangement, that clearness is the very last epithet which can be applied to his expositions on paper. His orthography and grammar are too often villainous. This sort Oxford has determined to have nothing to do with, and no true friend of science would wish to shake the determination. It may be doubted, however, whether the particular means of exclusion which are adopted, viz. insistence on a knowledge of Greek accidence, are altogether appropriate. It is quite possible for a man to have plenty of miscellaneous information, a good literary style, and originality of thought, without knowing as much of the Greek irregular verbs as would enable him to pass the ordinary college matriculation examination or responsions. The fact is tacitly admitted ; for, with a strange inconsistency, the same section of the University which shudders at the idea of abolishing the Greek test for men, has lately opposed the admission of women to the B.A. degree for this reason, amongst others : that it would involve their having to go through the same Greek course as men, instead of being exempt from it as at present. But if it is asked why Greek is essential to the culture of men and unessential to the culture of women, no answer is vouchsafed.

The amount of Greek required for responsions is only acquired by some—probably by the majority—of boys at the cost of an amount of time utterly disproportionate to the results obtained. For in the end, though they may scrape through examinations, they really know no Greek worth mentioning, and what little knowledge of it they may have acquired is so fugitive that in a year or two after the examination they could not conjugate a Greek verb, and would be lost if they attempted to construe the easiest passages from Xenophon. It is idle to say that this modicum of fugitive knowledge is essential to culture. The Greek test is in a great number of instances a complete failure, and the imposition of it serves only to prevent many boys from attaining to culture by means suited to their natural aptitudes.

It is largely due to Greek that the numbers of the science school at Oxford are kept in check. If the University seriously wished the school well, it would allow elementary science, together with a modern language, to be offered as an alternative to Greek in responsions, and colleges would follow suit in their entrance examinations. Were this done, a large number of boys, freed from the trammels of a study which is repellent to them, would be able to learn enough of science to qualify for a science scholarship, and would in addition be able to acquire a knowledge of English and French or German literature sufficient to entitle them to the designation of scholar in the widest sense of the term.

To turn to the question of fellowships. They may be regarded as possible encouragements to science in two ways—prospective and actual. No doubt the prospect of obtaining one out of a considerable number of fellowships in any given subject will attract clever undergraduates to that subject. The actual holder of a fellowship may be supposed to exercise considerable influence in his college in favour of the subject which he professes. Nearly all the science professorships are attached to fellowships in one college or other, and in addition there are thirteen scientific Fellows receiving emolument in various colleges. Therefore it would appear that, in point of influence in college counsels, Oxford is not so very badly off. But the outside world is apt to over-estimate the influence which a Professor-Fellow or an ordinary Fellow exercises in educational matters, unless indeed he be a man of exceptional force of character. Educational questions rarely come before a full college meeting. The control of studies in each college is vested in the few Fellows who are tutors, whose function it is to exercise a general supervision over the moral and intellectual well-being of undergraduates. This supervision has been formed into a system of which it is not too much to say that it is in the highest degree inimical to science. It is quite unlike the system which exists under the same name at Cambridge, and exercises a much greater pressure on undergraduates.

Every freshman on arrival is assigned to a tutor, whose business it is to set him on a course of study, to see that he goes to the proper lectures, that he is punctual in his attendance at them, and attentive to his reading. A tutor may or may not, as the case may be, undertake also the private instruction of his own pupils. Since there are many avenues to the art's degree, it might be supposed that the tutor would point out to each freshman the various courses of study open to him, would give him the choice of any one of them, and the necessary information as to the proper mode of following up his choice when made. Were this done, there is reason to believe that a much larger proportion would select natural science. But the freshman is not invited to make a selection. Scholars, whether classical, mathematical, or scientific, are sent at once to their respective subjects. A commoner, if of more than average ability, is told that he must read for honours in classical moderations, and afterwards for "greats" ; if of average capacity, then law or history is indicated ; if of lesser ability, the prescription is pass moderations with two pass classical schools, and probably political economy for the third. Neither honour men nor pass men hear of science unless they make particular inquiries about it ; and if they do, they are as often as not told that it will not give them the breadth of education necessary for their future careers. Instances can be cited of freshmen anxious to read science having been ordered to take a classical school instead.

Obviously this state of things would not exist if science were adequately represented on the tutorial staffs of colleges. It is most inadequately represented. Christ Church is the only college which shows to advantage in this respect. By reason of special endowments, it maintains three science lecturers, known as Lee's Readers, and of these the two senior are also tutors. There is a science tutor at Keble. (It is interesting, by the way, to note that the two most distinctively religious foundations in Oxford are those which give the most substantial recognition to science : it has not been discovered that their religious character suffers thereby.) In no other college is there a science tutor. There are lecturers, but the powers of a lecturer are not those of a tutor, either in theory or in practice. In some cases, indeed, the individuality of the lecturer may give him an influence coequal with that of the tutors, as is the case at Balliol and Trinity, and elsewhere, as at Merton, New College, Magdalen, and St. John's some considerable freedom of action is conceded to science lecturers ; but in other cases, the duties of the lecturer are limited to the arrangement of the work of such men as the tutors may send to them. Speaking generally, it may be said that the tutors

propose and dispose the courses of study; lecturers carry their behests into effect. The initiative is in the hands of the tutors who, with few exceptions, are classical, some few being mathematical, and only three scientific. By excluding scientific men from tutorships the Oxford colleges keep science at arm's length.

Three causes, then, militate against the increase of the scientific school at Oxford: the absence of any test of scientific acquirements in responsions and in most college entrance examinations, the severity of the Greek test, and the exiguous number of science tutors in colleges. These causes might easily be removed, but Oxford does not remove them, and, as a whole, it is unwilling to do so. At the bottom of it there is the wish that it should remain in the present what it has been in the past—the home of classical studies and of metaphysical philosophy. There may be those who would maintain that a university has the right to determine what courses of study should be characteristic of it. But it may be urged that the function of a university is not to be exclusive. Should it not rather be its duty to recognise and bestow its approval on the intellectual movements which have done, and are doing, most for the advancement of mankind? He would be singularly blind to what is going on around him who would deny that natural philosophy has been the great intellectual movement of this century, and that its methods and conclusions have been forced, willy-nilly, on every form of study that exists. But blindness seems to be prevalent among the majority at Oxford, or if not blindness, then wilful obstinacy. For its graduates, in their capacity as members of the University, have been obliged to give public sanction to science, and to spend large sums of money in making provision for teaching it. But in their more private capacities, as Fellows of Colleges, they stultify themselves by stopping the stream at its fountain-head. The endowments of colleges were given for the advancement of religion and sound learning. In times gone by sound learning meant Greek, and why? Because Greek literature contained not only all the metaphysical, but also all the natural philosophy known to the world. It is long since Artistotle has ceased to be the authority in natural, that he still is in metaphysical, science. But in the course of change the authorities have clung to Aristotle, and the endowments which originally were devoted to all sections of his work are now confined to only a part of them. The schoolmen, Duus Scotus amongst them, argued with as much subtlety about the scientific as about the logical teachings of Aristotle, and in so far imitated the spirit as well as the letter of the Greeks. Nowadays the letter remains, but the spirit is lost to the classicists, and has gone over, deprived of its material endowments, to science. How much longer will Oxford cling to the belief that it is the language in which they wrote, rather than the spirit in which they worked, which made the Greek philosophers the fathers of thought? It is indeed a curious satire on a modern classical education that the very things in which the Greeks were most interested are those which the Greek student of to-day most disparages.

It is to be hoped that Oxford will become awake to the unreasonable attitude which it has adopted towards natural science, unreasonable alike from the point of view of modern requirements and of the purposes of the philosophers whom it professes to venerate. For its own sake it is to be hoped that the awakening will come from within; if it does not, it will assuredly come from without. The University has just had a reminder of the dissatisfaction which was felt with the place assigned to science in its local examinations, and it has made haste to repair the defect. The dissatisfaction with its external examinations is as nothing compared with the growing dissatisfaction with its internal system, which, if left unremedied, must prejudice its reputation and destroy the influence which it possesses in the intellectual world.

Let it be said, in conclusion, that there are many at Oxford who are classical to the core, yet would willingly do all that is required for the advancement of natural science. They are mostly to be found among the middle-aged, not among the younger graduates. If certain actions of classical Oxford have been condemned in what precedes, exception is of course made of the more liberal minority, whose actions, if left unfettered, would be all that the most bigoted man of science could desire.

NOTES.

WE are informed that notification of the following additional delegates to the International Conference on the Catalogue of Science has now been received at the Royal Society:—Austria: Prof. Ernst Mach, Prof. Edmund Weiss. Germany: Prof. Walther Dyck (Munich), Prof. Van 't Hoff (Berlin), Prof. Möbius (Berlin), Prof. Schwalbe (Berlin), Oberbibliothekar Wilmanns (Berlin). Norway: Dr. Jorgen Brunchorst. The list of delegates is therefore now a remarkably complete and full one.

SIR GEORGE BADEN-POWELL has completed his arrangements for taking an observing party to Novaya Zemlya to observe the forthcoming solar eclipse. He will be accompanied by Dr. Stone, of the Radcliffe Observatory, Oxford, and Mr. Shackleton, of the Solar Physics Observatory, South Kensington.

AMONG the Civil List pensions shown in a return just laid upon the table of the House of Commons, we notice a pension of £200 to Mrs. Huxley, one of £120 to Mr. James Hammond, and one of £120 to Mr. Oliver Heaviside.

PROF. VAN DE SANDE BAKHUYZEN, Professor of Astronomy in the University of Leiden, has been elected a Correspondant of the Section d'Astronomie of the Paris Academy of Sciences.

DR. SAMUEL WILKS, F.R.S,, President of the Royal College of Physicians, has been appointed one of her Majesty's Physicians Extraordinary, in the place of the late Sir George Johnson.

THE death is announced of Prof. A. G. Stoletow, Professor of Physics in the University of Moscow. Prof. Stoletow was the author of several important memoirs on magnetism and electiicity, the velocity of sound, the critical state, and other physical subjects.

SIR JOHN PENDER, who was for many years prominently associated with the promotion of submarine telegraphy, died on Monday. It was largely due to his enterprise and faith in the practicability of laying a submarine wire between England and America, that the capital required to lay the Atlantic cable of 1866 was subscribed. He also took a leading part in the organisation and development of the Mediterranean, Eastern (India and China), Australian, South African, and Direct African cables. It is stated that the cable mileage of the submarine telegraph companies over which he presided at the time of his death amounts to 73,460 nautical miles.

NOTHING is safe from syndicates of speculators. From a question asked in the House of Commons on Tuesday, it appears that an attempt is being made to exclude the public from right of way to the Giants' Causeway. Unfortunately that great natural wonder is not public property, and cannot, therefore, be protected from the syndicate which proposes to interfere with the right of access to it.

THE distribution of prizes to the students of the Charing Cross Hospital Medical School will take place next Tuesday,

July 14. The Hon. Mr. Justice Vaughan Williams will occupy the chair.

The geological collection at Peel Park, Salford, which some years ago was withdrawn from public view, has been entirely rearranged, and was reopened last week. The process of re-arrangement has been carried out by Mr. Herbert Bolton, of the Manchester Museum. The collection is now in a condition which will make it of service to students, and it will doubtless become an important factor in the educational progress of the borough.

A telegram from Sir Walter Sendall, High Commissioner for Cyprus, reports that incessant earthquake shocks have been felt there for several weeks, causing great alarm and interruption of business. A Reuter telegram from Larnaca, dated July 6, says: "Violent shocks of earthquake continue to be felt in the island. A general panic prevails at Limasol, and the Government and military authorities are providing tents for the people. Permission has also been given to families to take up their quarters in the commissariat huts and camp at Polymedia. The town is deserted, and the Government offices, the bank, and the telegraph office have been installed under canvas."

Mr. John Milne writes us, that between June 23 and 31 he recorded several earth disturbances, which from their character had apparently originated at great distances. One commencing at 9h. 2m. 35s. G.M.T., on June 29, is probably identical with the earthquakes which on that evening shook Cyprus. With regard to the records of Prof. Vicentini of Padua, which in Japan mean time occurred at about 8.30 p.m. on June 15, and 5 and 9 a.m. on the following morning, he remarks that he only recorded the former of these on the 16th—his instrument being dismantled for adjustments to correspond with those of a second instrument which that day was installed at Carisbrooke Castle. Certain telegrams tell us that the sea waves on the coast of Japan took place on June 17; but this information, which, it will be observed, does not accord with what was noted in Europe, has not yet been confirmed.

The highly poisonous nature of acetylene has suggested to M. Chuard the possibility of employing carbide of calcium as an insecticide for agricultural purposes. M. Chuard proposes to try thoroughly mixing the carbide with earth, so that under the influence of moisture acetylene would be slowly given off at the roots of plants, thus preserving them from attack. At the same time, the bye-products, consisting of chalk and a little ammonia, would have a beneficial effect on the soil. It is proposed to try this method against phylloxera. Whether this would succeed equally well in all weathers, wet or dry, is quite another question.

In the *Annales de micrographie*, M. Miquel gives statistics for ten years of the numbers of bacteria in a cubic metre of air, both in the centre of Paris and in the park of Montsouris. In consequence of local improvements, the air in the park has gradually become purer, the number of bacteria having decreased from 480 per cubic metre in 1884 to 275 in 1893; but the air in Paris itself has increased in micro-organisms from 3480 in 1884 to 6040 in 1893. This large increase M. Miquel attributes to the greater cleanliness of the inhabitants, who, by dusting out and cleaning their houses and shaking carpets, &c., stir a large quantity of germs into the air. He even goes so far as to condemn this form of cleanliness on the ground that the germs are simply blown about by the wind, and find their way into the houses again, so that if you do not get your own germs back, those from your neighbours fly in at the window instead.

It is nearly ten years ago that Dr. Carl Auer von Welsbach first enunciated the property of rare earths, which led to his discovery of the incandescent light. In a contribution to the *Atti della R. Accademia dei Lincei*, Signor Enrico Clerici now considers the action which takes place when vegetable tissues are soaked with solutions of certain salts, such as are used in the preparation of incandescent mantles, and the organic matter is afterwards removed by calcination. It appears that if sections of wood are treated in this manner with nitrates of certain metals, and the ashes are examined under the microscope, every detail of the original tissues is found perfectly preserved, even down, for example, to the scalariform ducts of *Pteris aquilina*. The author compares this process with the petrifaction of fossil woods, and he concludes that we have here a phenomenon of molecular interposition with which it is possible to cause certain insoluble and refractory oxides to penetrate into cell-walls and vegetable fibres, and to transform them in the course of a few minutes into true petrifactions.

The anxiety of German municipal authorities to attract men of science to their cities and retain them there, is exemplified by a note in the current number of the *Lancet*. It may be remembered that in 1890, when Prof. Koch made his announcement respecting tuberculin, a special institution was founded by Parliament, under the name of the Royal Institution for Infectious Diseases, in order that he might be enabled to continue his researches on the treatment of such diseases on a larger scale than before, and it was placed entirely at his disposal instead of being controlled by the university, like all the other scientific institutions. It was, in fact, a special hospital in which new methods of treatment were to be tested, and it also contained a large laboratory, provided with every requisite, where not only Prof. Koch and his staff, but a number of other medical men carried on scientific work. The Government having lately announced that the Institution would possibly be removed from Berlin, the town council of Frankfurt offered to provide Prof. Koch with ample laboratory and hospital accommodation if he would agree to settle in their city. But when these negotiations became known, the medical as well as the lay press urged the Government to take measures to retain this important establishment in the metropolis, and an arrangement has now been made according to which the Institution is to be attached to the new Berlin Municipal Hospital at present in course of construction. The laboratory department will be built and furnished by the State, whilst the wards for infectious diseases belonging to the hospital are to be placed at the disposal of Prof. Koch by the municipal authority. This arrangement was strongly supported by Prof. Virchow, who is a town councillor, and it will, says our contemporary, undoubtedly have the approval of the medical men of Berlin, anxious as they are not to lose so celebrated an investigator as Prof. Koch. The spectacle of the London County Council holding out advantages to a man of science in order to dissuade him from migrating to another city awaiting to receive him with acclamation, is one which we are unable to imagine.

Last autumn a mysterious disease appeared amongst the poultry-yards in Rome, and was of so virulent a type that it produced a mortality of about 60 per cent. amongst the fowls which it attacked. Careful investigations could not identify it with the fowl-cholera of Perroncito and Pasteur, or with the cholera of ducks described by Cornil, or indeed with any other of the diseases hitherto bacteriologically associated with feathered animals. Dr. Salverio Santori, of the Laboratorio medico-micrografico del Comune di Roma, has recently published in an Italian hygienic journal the investigations which he has carried out as to the nature and origin of this epidemic. His results are extremely interesting, for he has succeeded in isolating,

not only a new pathogenic micro-organism, but one which belongs to the class of pigment-producing bacteria, the latter being but rarely associated with disease. In consequence of the splendid red colour it elaborates in artificial culture media, he has called it *Eritro-batterio*. In its microscopic appearance, and indeed in many other respects, it resembles the well-known *B. prodigiosus*, but it differs from the latter in its extreme virulence when subcutaneously inoculated in very small quantities into white rats, guinea-pigs, rabbits and fowls, death ensuing in from twelve to eighteen hours when liquefied gelatine-cultures are employed. When introduced *per os*, death is postponed for sometimes two months; but during the last ten or twenty days of the animal's existence, its extremities are completely paralysed. In both cases the microbe is found in the blood and all the organs of the body, but more especially in the fluids of the peritoneal cavity. It fails to elaborate its pigment in the absence of air, or when exposed to a temperature of 37·5° C., although it grows abundantly, and its virulence is not in the least diminished. Its pathogenic properties rapidly disappear in artificial cultures, often after a week; and the best method of preserving its virulence was found to be soaking silk threads in cultures, and letting them dry. Under these conditions, its virulence was preserved for three or four months. No immunity was induced in animals by administering gradually increasing doses of the toxine elaborated by it in broth. When exposed to the direct rays of the sun, in drops of broth enclosed in a Petri dish, it was destroyed in from eleven to thirteen hours.

"LEFT-HANDEDNESS in North American Aboriginal Art" is the subject of a short essay, by Dr. D. G. Brinton, in the May number of *The American Anthropologist*. He finds that a preference for the right hand and side has existed in the majority of mankind from earliest times, though not always in the same degree, and concludes that the ultimate reason for it is to be found in the erect posture of man. "The Anthropoids and other primates closest to men are ambidextrous, displaying no preference for either hand. But the erect posture introduces a new distribution of force in the economy; it opposes the powerful retardation of gravity to the distribution of the arterial blood above the level of the heart. The great arteries arising from the aorta carry the blood in an appreciably shorter course, and in less time, to the left brain than to the right. Its nutrition, therefore, is the more abundant, and its vitality the more active of the two hemispheres. Hence the right side of the body, which it controls, is more ready to respond to a stimulus on account of its higher innervation." There is also a short note on this subject, by O. T. Mason, in the June number of the same journal.

PROF. FRANK N. CUSHING'S expedition to explore the neighbourhood of Pine Island, of which mention was made in NATURE several months ago, proved extremely successful. Prof. Cushing has just returned laden with rare and interesting archæological specimens, and bringing the story of discoveries which demonstrate the existence of a prehistoric people in South-western Florida and the neighbourhood, who have left a multitude of mounds and other structures of couch shells, and whose works seem to furnish the key to much that was inexplicable in American archæology. He says that this ancient people differed in many ways from any others hitherto known; but that they somewhat resembled the Swiss lake-dwellers in their mode of life, and that their state of culture was quite similar and equal to that of the mound-builders and the Mayas and other builders of the ruined cities of Yucatan and Central America. Innumerable islands were found covered with shell foundations, and some with structures covering hundreds of acres, and rising fifty to sixty feet above the sea. A low mound, sixty feet in diameter, near Tarpon Springs, was thoroughly explored; more than six hundred skeletons were found, besides a large quantity of pottery, stone and other objects of art. At Marco, near the southern end of the Florida Peninsula, extraordinary painted tablets were found; also many carved wooden vessels, and implements and utensils of shell and bone. Sections of the shell islands made below the gulf level showed them to be entirely artificial, and the result of slow and long-continued building. The civilisation developed on these islands is supposed to have extended southward to Yucatan, and northward to the abode of the mound-builders. A notable collection of masks was found, put away in sets, each with an appropriate animal figure-head, designed foruse by priests performing the myth drama. The shell structures of the Ten Thousand Islands, as well as those on the mainland, are covered with peat and dense growths of mangrove, cactus and other tropical vegetation. The general plan is similar in all. There is a network of enclosures of various sizes, or ridges leading up to terraces crowned by gigantic mounds. A series of level-topped pyramids surround two or three lakes, from which channels lead out to the sea. The resemblance to the ancient cities of Yucatan is striking and instructive. The explorations made lead to the inference that the Ten Thousand Islands are nearly all artificial.

THE publication of the *Annals* of the Russian Central Physical Observatory for the year 1893 has enabled Dr. Hann to collate the mean temperature conditions of Verchoyansk, in Russian Siberia, from observations extending from nine to eleven years. The position of this place, which from the extraordinary lowness of the winter temperatures has become classical from a climatic point of view, is 67° 34′ N. lat. and 133° 51′ E. long. We extract the following remarkable records from the *Meteorologische Zeitschrift* for June. The figures refer to the lowest monthly means, and the absolute minima, respectively: November −47°·6, −72°·4; December −63°·0, −82°·8; January −71°·1, −90°·0; February −72°·0, −93°·6; March −43°·2, −77°·4. The extraordinary minimum for February has been quoted previously; it occurred in 1892, and is supposed to be the lowest reading recorded in any part of the globe. The mean yearly temperature, corrected for diurnal range, from values calculated by Dr. H. Wild, is 1°·0 F.

AT the meeting of the French Meteorological Society on the 2nd ult., M. Angot communicated a summary of five years' observations on the velocity of the wind at the top of the Eiffel Tower and at the Central Meteorological Office. These observations fully confirm results previously obtained, and show that the diurnal variation of the wind on the tower is quite different from that observed near the ground. The velocity is nearly constant during the night, slackens during the early morning, and reaches its minimum in the afternoon. Near the ground, on the contrary, it is known that it freshens soon after sunrise until early in the afternoon, and then decreases regularly during the night. These results show that this variation is only a phenomenon peculiar to the lowest strata of the atmosphere. It is interesting to note that it is only necessary to ascend about 1000 feet to meet with the conditions known to exist on mountains, viz. maximum and constant velocity during the night, and decrease of velocity during the day, under the influence of the vertical motion of the air due to the heating of the soil.

WE are glad to call attention to the publication of Part iv. (vol. iv.) of the *Transactions* of the Leicester Literary and Philosophical Society. Among the contents we notice: "Notes on the Swiss Flora," by Mr. G. C. Turner; "Note on a Dermoid Tumour from a Frog," by Mr. F. R. Rowley; and "A Comparison between the Lepidoptera of Japan and Great Britain," by Mr. W. J. Kaye.

FOUR new volumes have appeared in the Encyclopédie scientifique des Aide-Mémoire series. In one of these—"La Spectroscopie"—Prof. Julien Lefevre briefly describes the application of spectrum analysis to physics, chemistry, physiology, and astronomy. The different methods employed for the observation of emission and absorption spectra in the laboratory, the solar spectrum, and the constitution of radial movements of stars are described, and a chapter is devoted to phosphorescence and fluorescence. The study of prisms, spectroscopes, and the theoretical side of the subject is treated in a companion volume—"Spectrométrie-Appareils et Mesures"—in the same series. A third volume recently received is entitled "Attaque des Places," by Lieut.-Colonel E. Hennebert. In it the various methods of besieged and besiegers, in past and present times, are set forth for the instruction of military engineers. MM. H. Moissan and L. Ouvrard have contributed to the series a valuable little volume on nickel—"Le Nickel." They describe in succession the physical and chemical properties of nickel, the principal compounds, minerals containing nickel, the metallurgy of nickel, alloys, extraction of nickel by electrolysis, and the principal applications of the metal.

THE additions to the Zoological Society's Gardens during the past week include two White-tailed Deer (*Cariacus leucurus*, ♂ ♀) from Canada, presented by Mr. Richard R. Dobell; a Red-bellied Squirrel (*Sciurus variegata*) from Vera Cruz, presented by Mrs. G. Maria Pullen; a Blue-fronted Amazon (*Chrysotis æstiva*) from South America, presented by Mr. A. E. Corsbie; a Black-headed Gull (*Lorus ridibundus*), European, presented by Mr. James Boorne; a Peregrine Falcon (*Falco peregrinus*), caught off the coast of Terra del Fuego, presented by Mr. T. W. Hubble; two Spotted Salamanders (*Salamandra maculosa*), European, presented by Mr. Philip Gosse; a Chimpanzee (*Anthropopithecus troglodytes*), a Temminck's Pangolin (*Manis temminckii*) from West Africa, two Ostriches (*Struthio camelus*, ♂ ♀) from Africa, a Blood-breasted Pigeon (*Phlogœnas cruentata*) from the Philippine Islands, two Hamadryads (*Ophiophagus elaps*), two Indian Pythons (*Python molurus*) from India, three Naked-necked Iguanas (*Iguana delicatissima*) from Tropical America, a Great-billed Rhea (*Rhea macrorhyncha*) from Brazil, deposited; a Crested Pigeon (*Ocyphaps lophotes*) from Australia, purchased.

OUR ASTRONOMICAL COLUMN.

BROOKS'S PERIODIC COMET.—The following search ephemeris for this interesting comet is from a complete one in *Astr. Nach.*, 3361:—

1896.	App. R.A. h. m. s.	App. decl. ° ′ ″	Brightness.
July 11	22 37 59·13	18 8 51·3	1·06
15	39 0·64	18 9 52·8	1·14
19	39 35·58	18 12 28·2	1·22
23	39 43·58	18 16 28·1	1·31
27	39 24·50	18 21 40·9	1·40
31	22 38 38·45	−18 27 52·2	1·50

Following the above table, the comet should be looked for soon after midnight about 11° north of the 1st mag. star Fomalhaut, which is on the meridian about 3.30 a.m.

MAGNITUDES OF SOUTHERN STARS.—In vol. xxxiv. of the *Annals of the Astronomical Observatory of Harvard College*, a complete and graphic description is given of the expedition sent out from the observatory at Cambridge, Mass., to South America, in order to extend the work of the Harvard Photometry to the stars of the southern hemisphere. Mr. S. I. Bailey, assistant professor of astronomy at the College, was the observer chosen for this duty, and in the report gives an historical account of his journey southward, which began on February 2, 1889, his only companions being his wife and son. Guided partly by the information furnished by the inhabitants respecting the meteorological conditions of the country, he at last decided to erect a station in Peru, choosing a spot on the summit of a mountain 6600 feet above sea-level, about eight miles north of east from the Chosica station of the Oroya railway. The observations have all been taken with the meridian photometer used for the northern stars, described in vol. xxiv. of the *Annals*. The instrument has two objectives, each of 10·5 cm. aperture and 166 and 145 cm. focal length respectively. Magnifying powers of twenty-eight and twenty-four diameters were used in the measurements. The magnitudes have been obtained by comparing each star separately with σ Octantis, mag. 5·5, this being the brightest star in the neighbourhood of the south pole. The first series of observations were taken on May 24, 1889, and for several months after this the weather proved very favourable, the instrument being used on nearly every clear night. As the summer season of the southern hemisphere approached, clouds became more frequent, and at length almost every evening was cloudy. This being so, the instrument was dismounted, and the observers travelled further southwards, remounting the photometer at a mining village called Pampa Central, near Valparaiso. In March 1890, they returned to Chosica, and again mounted the instrument in its old position, but the weather not proving so suitable as in the previous year, they again removed in September, and set up the station at Arequipa. Thus the measures of the various stars have been made at four stations. Following this introductory description, comes the voluminous catalogue of the magnitudes of 7922 southern stars, arranged on the same plan as the Harvard Photometry for the northern hemisphere.

RUGBY OBSERVATORY.—From the report of the Temple Observatory, Rugby, we learn that double-star observations were continued during last year. These observations are in continuation of the series commenced by Messrs. Wilson and Seabroke in 1871, which now comprises about 5000 complete measures of distance and position angle. The measures have been regularly published. The working list of double stars, which forms part of the report, gives approximate positions and measures for purpose of identification, and will be very useful to other observers who are following the same line of research. The observatory was open on eighty-three nights for the instruction of members of the school.

HARVARD COLLEGE OBSERVATORY.—Prof. Pickering has made the issue of the fifteenth annual report the occasion for furnishing some interesting particulars as to the establishment of Harvard College Observatory, and stating the general policy of the management. One of the statutes states that "the objects of the observatory are to furnish accurate and systematic observations of the heavenly bodies for the advancement of astronomical science, to co-operate in geodetical and nautical surveys, in meteorological and magnetical investigations, to contribute to the improvement of tables useful in navigation, and, in general, to promote the progress of knowledge in astronomy and the kindred sciences." It is noteworthy that no reference is made in the statutes to teaching, and the observatory is therefore primarily an institution of research, although such teaching as does not interfere with the regular work has been undertaken. While precise measures of position have not been neglected, the policy has always been to specially study the physical properties of the stars and other heavenly bodies, since less attention is usually paid to such work than to meridian work in most observatories. Accordingly much attention is given to photography, photometry and spectroscopy. Details as to the manner in which the various instruments have been employed are also given. The revision of the stars in the Harvard Photometry has been completed and is ready for publication, and it is worth noting that as many as 322 stars were observed on one occasion in the space of six hours, roughly one a minute; 107 photographs of the spectrum of β Lyræ have been lent to Prof. Frost for investigation, and this has suggested the possibility of increasing the usefulness of all the photographs which have been taken. Prof. Pickering invites correspondence with astronomers who may desire to borrow any of the photographs, and suggests the investigation of positions, distribution and brightness of stars in clusters, distribution of light in spectra, peculiar spectra, eclipses of Jupiter's satellites, and lunar mountains.

BAKU AND ITS OIL INDUSTRY.

NO city on this side of the Atlantic can show a more marvellous growth, within a short period of time, than Baku upon the Caspian; and, even apart from its petroleum industry, its natural advantages are so great, that it seems specially designed for a brilliant future as the emporium of the whole trade between European Russia, her Central Asian provinces, and Persia. So quick has been its expansion that, but an insignificant village of 1400 inhabitants thirty years ago, it can now boast a population considerably over 100,000, which is increasing yearly by leaps and bounds.

This rapid growth is mainly due to two causes: first, its magnificent harbour, well protected from the north by the extended horn of the Apsheron peninsula, and from the east by the Serpent's Island, which forms an efficient and natural breakwater; and in the second place, its immediate proximity to the main area of naphtha supply, which already rivals that of America, and promises in no distant future to become the exclusive market for all Asia, and also for the greater part of Europe. The commencement of the modern oil industry of the Caucasus dates from 1823, when the brothers Doubinin started a small works in the neighbourhood of Mozdak, which, owing to want of capital, they were forced to close in 1850. These pioneers were followed in 1836 by the engineer Voskoboinoff, who established a distillery at the foot of the mud geysers of Bog-Boga; but this effort proved likewise unsuccessful, and no trace of it now exists. Later, in 1859, M. Kokareff founded the Baku Petroleum Company, with the view of extracting the oil from the naphtha-impregnated soil; but experiment having shown in 1871 that the crude oil could be obtained by boring, this first method was abandoned, the artesian boring becoming universal. and a firm foundation was laid for the industry and for those marvellous developments which threaten an economic revolution in the lighting and fuel supply of a considerable portion of the world.

The year 1865 marks an important advance, a M. Witte having in that year established a manufactory of ozokerite on the Sviatoia Gora (Holy Mountain), and it was his engineer, M. Weisser, who, in that same year, established the first refinery in the town of Baku itself. So rapidly did the industry develop, that by 1873 the town was in danger of becoming entirely absorbed by the distilleries that rose on every hand, whilst the black, dense, and acrid smoke from the naphtha-fed furnaces poisoned the atmosphere. Baku, however, being under the influence of a despotic government, M. Staroselsky, the then governor, was enabled to effect a revolution, which, however drastic it may appear to our circumscribed democratic conceptions, was radical and efficacious. This consisted in issuing an edict that the refineries situated in the town were to be removed outside its limits, and for that purpose the corporation ceded certain town properties situated at a distance of about two versts. This land they divided into a series of blocks of from 2000 to 2500 square sargenes each (sargene is seven square feet English), and suddenly, as if by magic, eighty new works sprang into existence, their erection going forward at fever heat day and night until completed.

How intolerable the nuisance had become may be inferred from the fact that the sole firing material in use for boilers and distilling-tuns being the refuse oil, or so called astatki, and no smoke-consuming apparatus at that time being employed, not only the buildings, but the whole surface of the ground became coated with a thick layer of soot, whilst the roads were almost impassable owing to pools and ponds of oil. No wonder, therefore, that it should have received the name of the Black Town, (Tchornoia Gorod) a name which still clings to it, although through the introduction of an apparatus, by means of which steam under pressure and air are proportionately mixed with the naphtha residue, the smoke is now virtually consumed. As a result of this invention, the factories erected under the new conditions beyond the limits of the corporation land, notably Nobel's Villa Petrolia, and Popoff's Gardens, are perfectly clean. and this district in consequence has received the name of the "White Town."

Owing to the number of valuable bye-products obtainable, the refining process is complicated in its character, although the appliances used are very simple in their construction. The crude oil, fed through lines of pipes from the main sources of supply at Balachani, is stored in large iron reservoirs, from which it is drawn off to be treated in gasometer-shaped retorts. These being heated by steam coils to about 140° C., the products, having a low boiling point, such as gasoline and benzine, are separated, and passing into separate chambers are condensed. A further heating to about 150° C. in like manner separates the low-grade petroleums, which have been largely used in adulteration, and are so dangerous to the consumer. The third distillation becomes the petroleum of commerce, after having been washed and cleaned under treatment with sulphuric acid and caustic soda. The residues of heavy oils are generally treated in a separate establishment, and from them are extracted various grades of dyes, vaseline, lubricating oils, &c.; the demand for the latter constantly increasing, owing to their excellent quality and cheapness. The ultimate refuse astatki is likewise sure to become a keen competitor with coal as a fuel, a ton of this liquid being the equivalent of from two and a half to three tons of coal. To what uses it can be applied is well exemplified in the town itself: until very recently it was used for watering the streets, and not only is its employment universal in every kind of manufacture, but also for all heating and other domestic purposes. Its use is also rapidly extending on the railways in South Russia. All the steamers on the Caspian and Volga, and the locomotives on the Transcaucasian and Transcaspian lines, burn no other fuel; and when we regard its portability and cleanliness, it would seem to be but a matter of time for its advantages to be generally recognised. Owing to the abundance of the supply, at times millions of gallons have been allowed to run into the sea, or have been deliberately set on fire, and it is no exaggeration to assert that a full half of these vast supplies from nature's storehouse have been lost and dissipated unproductively.

Baku is pre-eminently a centre of commerce, and for residential purposes most undesirable, it being subject to heavy dust-storms, rainlessness, intense heat, and almost entire absence of vegetation and fresh water. The only garden is the so-called Alexander II., maintained at great expense, the shrubs and trees being planted in soil brought from Persia. A few fresh-water wells give a very limited supply, the usual sources being brackish; but the railway company supplement it by cisterns filled from the river Koura, and almost every steamer imports some from the Volga. A peculiarity in the distribution of the local supply is, that the few fresh-water wells are in close proximity to those impregnated with salt.

Varied as are the subjects of study presented by the town itself, the chief centre of interest is undoubtedly the plateau of Balachani-Sabountchi, situated about eight miles to the north-east of Baku, and connected with it by a branch line of the Transcaucasian Railway. When viewed from a distance the tall truncated towers erected over the wells seem in such close proximity to each other, that they present the appearance of a pine forest; and it is only on a closer approach, that they prove to be the derricks containing the machinery necessary for boring or the pumping of the oil. These pyramids consist of a wooden-boarded framework, and are easily removable when the bore becomes exhausted. How thickly they are grouped, may be inferred from the fact that, within the limited area of three square miles, over 400 of them are crowded. (Fig. 1.)

Not the least puzzling of the many enigmas presented by these wells, is the nature of the source from whence the oil is drawn. Enclosed in its subterranean prison it needs, in many instances, but an insignificant outlet to rise as a roaring fountain of sand and oil to a height sometimes exceeding 200 feet, continuing in action for days and even weeks, spouting forth during the time many thousands of gallons per day; yet this in no way interfering with the supply from closely adjacent wells, which continue to yield their normal quantity.

It is therefore evident that the sources are independent of each other, and that although the reservoirs may have been originally arranged in regular series, yet, through the strata having become dislocated and faulted, they now form separate and distinct chambers of varying capacity and without direct connection between them.

Small though the evidence, geology throws some light upon the probable structure of the basin, whereas chemistry reveals but little as to the origin of the oil.

Geologically the town of Baku is situated on beds of Quaternary age, which have received the name of Aralo-Caspian beds; whereas the main portion of the Apsheron peninsula, on the south side of which Baku is situated, consists almost exclusively of Pliocene and Miocene strata, subdivided locally into the Baku, Apsheron, and Balachani formations. Wherever the

rocks, which consist mainly of limestones and sandstones, are exposed, it is evident from their highly inclined dips, varying rapidly from point to point, that the whole region has been subjected to great earth-movements, the presence of overthrust faulting having been specially noted by Dr. Sjögren, of Upsala. As a result of these movements, the strata have been thrown into a series of anticlinal and synclinal folds, upon whose upturned and denuded edges throughout the Balachani district beds of Aralo-Caspian age have been unconformably laid down, a most notable feature connected with them being the extreme thinness and the abundance of the layers composing them.

Chemically, numerous suggestions have been made as to the origin of the oil. Mendeléef ascribes it to the carbon enclosed in metallic iron, deep seated in the earth's crust. Daubrée and Coquand connect it with combined chemical and eruptive action; Fuchs and De Launay lay special stress upon its relation to disturbed districts, whereas Lesquereux ascribes it without reserve to the decomposition of vegetable remains, and Hofer regards it as being of animal origin. Seeing, therefore, that the geological and physical characteristics lend support to all the theories enunciated, to none of them can as yet be granted any other than a hypothetical value.

Since the introduction of boring in 1871, this system has been exclusively employed. The number of the bores in 1881 reached 375, and in 1886 490, of which, however, only 160 were in actual work, 180 having become exhausted, and 150 being plugged down as reserves. The enormous supply of the crude oil may

FIG. 1.—General view of the Balachani Oil-field.

be gathered from the following figures. In 1832 the yield was only 150,000 poods (pood = 36 lb.) = 2000 tons; in 1867, 999,999 poods, = 14,500 tons; in 1880, 300,000; and in 1890, 3,100,000 tons. That the supply is not inexhaustible, may be inferred from the fact that the depths of the bores are being progressively increased. We thus find that in 1871 the oil was reached at 70 feet, in 1873 this increased to 120 feet, in 1883 to 450 feet, in 1886 to 700; whilst a later bore, sunk to a depth of 1000 feet, has yielded no oil. It is evident, however, from the cellular character of the oil-bearing strata, and the immense supplies already obtained from a very limited area, that the period of exhaustion is indeterminable, and any conjecture baseless.

The means employed for raising the oil are of the simplest character; pumping, as understood in the ordinary acceptation of the term, is, owing to the depth of the bore, of course impracticable, so that after cessation of the flow consequent on the exhaustion of the gas, copper tubes called "jalonkas" are employed. These cylinders, about 12 feet long, are provided with a valve opening inwards on touching the bottom of the bore, and close on the tube being lifted filled with the oil. On reaching the surface the jalonka is lowered on to a platform, thus pressing in the valve and releasing the naphtha, which flows in a greenish-tinted stream to reservoirs connected by pipe-lines with the refineries in Baku.

It will be readily understood that in a district so saturated with naphtha oils, there must be an ever-present danger from the ignition of the exhalations of hydrocarbon gas, which escape not only from the bores, but through every fissure and cleft in the soil; and although every possible precaution is taken against such a catastrophe, many disastrous fires have occurred. Our illustration (Fig. 2) is from a photograph of one that took place in 1887, which was specially notable for its duration and devastation, all the derricks within a considerable area having been consumed, and all efforts to extinguish it failing until the volume of gas had become weakened and it burnt itself out.

These exhalations are most powerful in the district of Surachani, where the natural gas is made use of for lime-burning, for every domestic purpose, and as fuel for the boilers; in fact, it is only necessary to sink a pipe a few feet into the soil to obtain on ignition a flame of considerable length, and this is practically shown at the works of Messrs. Kokareff, where one such has been burning many years.

Adjoining this refinery, and placed by the Russian Government under that firm's special protection, is the ancient and celebrated temple of Zoroaster, which for over 2500 years was the sacred resort for pilgrimage of the Guebers, or fire-worshippers of Asia. (Fig. 3.) Formerly a flourishing monastery,

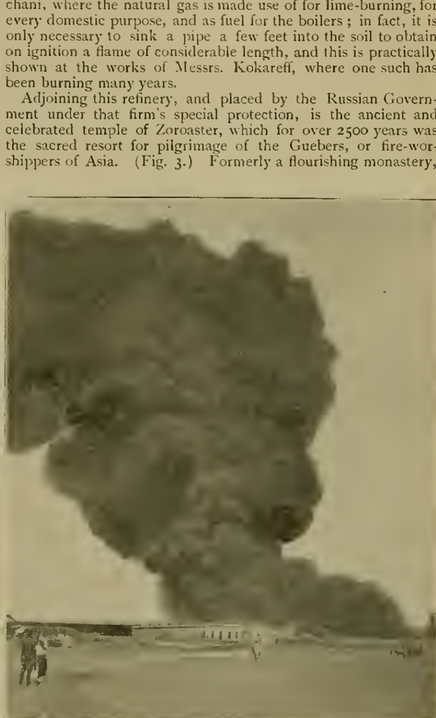

FIG. 2.—An Oil-well at Balachani on fire.

to-day it is but a decaying and deserted monument of the old religion of the Parsees. It consists of a large square courtyard enclosed by the cells of the monks, all opening inwards. A double-storied erection in the front was the dwelling-place of the chief priest, beneath which, and closely adjacent, was the chapel cell, on whose rude stone altars burned the Eternal Fires. In the centre of the courtyard is a square building, flanked with four towers, from which the flames ascended, and the arched recess in the basement was used as a crematorium wherein, by means of the sacred fires, the bodies of the faithful devotees were consumed. It is not only on land, however, that natural gas is abundant; a favourite excursion of the inhabitants and visitors being to take steamer on a calm dark night to the neighbourhood of the Baibat Point, where the gas rises through the waters of the Caspian sea in bubbling eddies, which, on being ignited with burning tow, covers the water with flames over a considerable area.

Although owing to its prominent position and natural advantages the attention of Europe has been mainly concentrated on the district and town of Baku, it must not be forgotten that this is but one out of many important petroleum fields awaiting

development in South-eastern Russia. Not only are there rich deposits known to exist in immediate proximity to the sea in the Transcaspian province, but an immense area of petroleum-producing strata extends from the Crimea to the Taman peninsula, and thence across the northern boundary of the Caucasian range to Petrovsk upon the Caspian, and many centres of production in these districts are now being opened up, which must shortly come into keen competition with the Baku industry. Already during many years oil has been extracted from borings in the Kouban district, whence by means of pipe-lines it is transported to a refinery at Novorossisk; but these will

FIG. 3.—The Temple of Zoroaster.

be insignificant when (should all the reports be confirmed) the wells at Groznaia and its neighbourhood are tapped, it being considered that they will rival, if they do not surpass, Baku in productiveness. It would appear that the beds are almost identical in age to those of the Balachani-Sabountchi areas, and it would be an interesting subject for future study to ascertain if the line of petroleum productiveness to the north of the Caucasus follows that of the depression which in a former period connected the waters of the Caspian with those of the Azoff, the Black Sea, and the Mediterranean.

The accompanying illustrations are reproduced from an excellent series in *Globus*. W. F. HUME.

A SEISMIC SURVEY OF THE WORLD.

THE principal object of a seismic survey of the world is to measure the velocity with which earthquake motion is propagated through its crust, and possibly through its interior, and from the resulting figures to give to astronomers and physicists additional data respecting its effective rigidity.

It is the converse of the answer to a problem which in 1889 was incidentally worked out by Lord Kelvin, who, assuming a certain rigidity for our earth, determined the rate at which vibrations were likely to be transmitted through the same, the object of the calculation being to compare the result with that obtained from observations on an earthquake which in that year, originating in Japan, had been noted at many stations n Europe. The feasibility of the proposed undertaking and the probability of its yielding satisfactory results are based upon the existence of observations of the following nature.

For many years past astronomers, and those in charge of self-recording magnetographs, have observed disturbances in their instruments at varying intervals after the occurrence of an earthquake in some remote locality. In 1867, about seven minutes after an earthquake in Malta, M. Wagner observed at Pulkova an oscillation of 3″ in a level. One hour and fourteen minutes after the great earthquake of Iquique on May 10, 1877 (effects due to which were observed by the writer in Japan), at the same observatory M. Nyren noted oscillations in the bulb of a level of 2″ which had periods of 20 seconds. The late Dr. E. von Rebeur-Paschwitz repeatedly observed and obtained records of earthquakes which had their origin at distances equal to or more than one quarter of the earth's circumference from his observing stations. Vicentini, Agamennone, and others provided with instruments sensible to slight movements of the earth's crust, have made similar records; whilst the writer has not only shared in contributing to this class of observations, but on one occasion at least has obtained satisfactory photograms of a disturbance originating at his antipodes.

The conclusion which may be taken as well established by these observations is that suitable apparatus placed in any part of the globe will record the movements due to severe earthquakes originating in any other portion of our globe, and therefore there is nothing unreasonable in saying that every observatory throughout the world, if it were equipped with proper instruments, would be in a position to contribute to the knowledge of changes which are continually taking place, not only beneath the land, but also beneath the ocean.

For a person or a community to imagine that they reside in a locality free from earthquakes, is one of the greatest of modern fallacies. Although movements may not be felt, all places are disturbed in a manner capable of being recorded very many times per year. In addition to earthquakes the focus of which may have been some thousands of miles distant, to the recording of which the present note is intended to draw special attention, unfelt disturbances of a local origin may be recorded. Even at places where shocks are unknown, excepting as rare events recorded in ancient history, these may sometimes average two a day. Other movements taking place beneath our feet are slow diurnal tiltings, annual variations in the vertical, tremors of probably two distinct characters, earth pulsations and elastic vibrations.

To designate all these movements, which vary in their periods between the fraction of a second and twelve months, as "earth tremors," and an instrument to record them, a seismograph or a tromometer, are evidently misnomers. Although a single instrument may be obtained which will give information about each of these movements, experience has shown that it is better to have a particular instrument for a particular purpose. To record rapidly recurring vibrations the most sensitive arrangement that is self-recording is, perhaps, a Perry tromometer, which will detect the disturbance produced by a moving train at the distance of a mile. To record slight changes of level in a district, such, for instance, as may accompany changes in barometric pressure, a bifilar or horizontal pendulum, which is nearly as insensible to elastic tremors as a Perry tromometer is to change of level, would be best.

What is wanted for a seismic survey of the world is an instrument that is sensible to the preliminary elastic tremors of an earthquake, and then to the slowly recurring quasi-elastic gravitational waves by which these are followed. For this purpose it appears that our choice rests between some form of ordinary pendulum apparatus, like that of Agamennone or Vicentini, or some form of horizontal pendulum. Whatever form is selected, each instrument must be similar and similarly adjusted. If this is not the case, then at each station different instruments may commence to move with different phases of motion, and the records for purposes of comparison are without value. For example, an earthquake may originate at a known locality, at a known time, and be recorded at twenty different observatories in Europe, at each of which good time is kept, but at each of which the recording instruments are different in character.

The result of the calculations based on these observations have shown, in one instance at least, that the velocities of propagation of motion from the origin to each of these stations have varied between 2 and 20 km. per second.

The cause of this apparent discrepancy lies in the fact, that at different stations, during a disturbance having a duration of perhaps several hours, the different instruments have commenced to move with different phases of motion. This is a source of error which has been thoroughly recognised by observers in Japan for the last twenty years, and by timing the rate at which a particular vibration has travelled between given stations, the apparently conflicting results to which we are otherwise led have been greatly reduced.

When an earthquake is observed at stations far distant from each other, it is no longer possible to identify a particular vibration at these stations; but what can be done, is to note the time at which the preliminary vibrations commence and the interval which follows before the undulatory motions appear. So far as observations have gone, the velocity of propagation of the latter movements varies between 2 and 3 km. per second, which is about the rate we should anticipate to be found for motion passing through the materials constituting the earth's crust. The velocity for the former, however, appears to vary between wide limits, 10 or 12 km. per second being about the average. Because this rate of transmission is greater than that at which motion could pass through glass or steel, the inference is that it may possibly pass *through* our earth, and because it is variable the idea suggested is, that the rate of transmission varies with

the depth of the wave path. Should this be so, the next suggestion is, that as a wave proceeds downwards refraction may take place, and that a focal concentration of energy may be found at the antipodes of a seismic centre.

From these remarks it is clear that amongst the most important work with which the seismologist has now before him, is to measure the speed at which the preliminary vibrations of an earthquake are transmitted, and because this is high, the definition on the recording surface must be clear, the rate at which this is moved must be such that time intervals may be measured to within 10 seconds, and the observing stations, if they are limited in number, should be widely separated.

In the choice of stations, at all of which there must be the means of keeping fairly accurate time, the plan originally suggested by the author was to choose these relatively to districts where large earthquakes are frequent. The districts selected were the South American coast, Japan, and the Philippines, Himalaya and Central Asia. By a system of trials it was found that fifteen stations could be chosen, nearly all of which happen to be in the United States or British colonies, about ten of which would form a series approximately 2000 miles and multiples of 2000 miles distant from any of the three districts.

With a series of this description, data of a fairly complete nature respecting the rate at which motion may be transmitted round and, possibly, through our earth at varying depth should be obtainable. Any addition to this series would naturally render our information more certain, and add to the value of records obtained from centres other than those specified.

The cost of installation at each observatory would be approximately £50.

The proposal here made is similar to one published by the writer in January 1895, and does not materially differ from the one put forward by that distinguished investigator, the late Dr. E. von Rebeur-Paschwitz, and now being so warmly advocated by Dr. G. Gerland of Strassburg (see pp. 135, 136).

J. M.

THE SPECIFIC GRAVITY OF THE WATERS OF THE SEA.

IN continuation of his paper on oceanic circulation, in the concluding volume of the *Challenger* Reports, which chiefly dealt with the distribution of temperature, Dr. Buchan has published in the *Transactions* of the Royal Society of Edinburgh a series of maps showing, so far as the present state of knowledge permits, the specific gravity of the waters of the great oceans at various depths; and accompanying the maps is an extended discussion of some of the points treated in the previous memoir.

In the paper just published, Dr. Buchan has departed from the mode of representing salinities and specific gravities employed in the *Challenger* Report, and instead of charting the actual values, gives the departures above and below an average assumed to be a mean for all the oceans. It is difficult to see that anything is gained by this method; and it has the undoubted disadvantage that any future change in the assumed means will involve the reconstruction of all the maps. Even at the surface there are considerable portions of the sea of which we can only guess at the mean temperature and salinity, and the general average given by Dr. Buchan may therefore undergo modification, notwithstanding the attempts to apply a process of integration. Below the surface, the general average is simply the mean of existing observations; and while an inspection of the map shows that these are by no means perfect, the fact that there is only a single line of observations in the North Pacific, one in the Southern Ocean, none in the Atlantic north of 40°, and none in the Indian Ocean, indicates that the general averages must be mere approximations. Another unsatisfactory effect of the adoption of this method is due to the fact that values above and below the general average are thrown into strong contrast by being printed in different colours on the maps, thereby frequently exaggerating their apparent difference. In the case of the North Pacific, for example, Dr. Buchan lays great stress on the low specific gravity of the waters of this ocean at all depths. Undoubtedly the observations show that they are lighter than the Atlantic by a quantity amounting below the surface to about 0·0008; but the fact remains that a change of, say, ·0003 in the mean for the globe at 300 fathoms would throw the whole of the North Pacific *above* the average, while the observations within that area themselves show inconsistencies amounting to double that quantity. We draw special attention to this point, because it seems to lie at the root of a certain weakness in the line of argument taken up by Dr. Buchan, leading to a confusion of what we may call the statical and dynamical problems of ocean circulation, somewhat analogous to that involved in Ferrel's theory of cyclones. In drawing up any general scheme of the movements of oceanic waters, it is necessary to keep clearly in mind certain "conditions of continuity"; if the surface salinity is anywhere reduced by copious rainfall, it must somewhere else be correspondingly increased by evaporation; if reduced by melting of field ice, a corresponding quantity of salt must have been added to the deeper waters where the ice was formed; if up-welling is produced by an off-shore wind, the same force must be competent to cause a down-draught somewhere else. These considerations seem to suggest several simplifications in the scheme of circulation proposed by Dr. Buchan.

Comparing the Atlantic and Pacific Oceans, we find in the former a limited area subject to atmospheric systems of considerable intensity, the air over a considerable proportion of the surface being relatively dry. Over the Atlantic there is accordingly a relatively great amount of evaporation, producing high surface salinity, and the water carried off is distributed over an area nearly four times as large as in the case of the Pacific, allowing of its gradual return. In the Pacific, on the other hand, the winds are not so strong, the rate of evaporation is slower, and the redistribution of the moisture more local. It may therefore be possible to account for a considerable part of the low salinity of the Pacific without assuming that the high rainfall of the East Indian region produces effects so markedly in excess of those due to the immense discharges of fresh water into the Atlantic or the Indian Ocean. Dr. Schott's observations in East Indian waters support this view, indicating that the great freshening due to heavy rainfall is here, as elsewhere, largely restricted to the immediate neighbourhood of the land.

As an example of the converse of the foregoing, we may take the case of the undercurrent flowing from the Mediterranean to the Atlantic through the Straits of Gibraltar. From the observations of temperature and salinity Dr. Buchan regards it as placed "beyond dispute" that the warming effect of this outflowing water "becomes strikingly apparent at about 500 fathoms," and "beyond this depth its influence is felt over nearly the whole breadth of the Atlantic to at least about 1000 fathoms." Now at the Straits of Gibraltar the depth is something under 200 fathoms, and the extreme width at the surface a little greater than the Straits of Dover; and it is known that the loss by evaporation from the surface of the Mediterranean is not nearly compensated for by the fresh water additions from the rainfall and the rivers which empty themselves into its basin. The amount of water issuing into the Atlantic must therefore be greatly less than the amount entering the Mediterranean, and a comparison of the volumes and temperatures of the two bodies of water shows that it is almost impossible to give the outflow from the Mediterranean credit for such widespread action.

The two cases we have quoted, perhaps the strongest of several suggested by Dr. Buchan's papers, seem to support the results of a number of recent investigations, indicating that the effect of differences of specific gravity, while by no means a negligible quantity, is in general small compared to the dynamical effects due to the momentum of the surface currents, even at great depths.

From this point of view, we at once obtain help from the researches of Pettersson and Krümmel, noting specially their results as to the tendency of surface currents to induce *reaction* currents under them, and to divide on changing direction, and bearing in mind the deflecting influence of the earth's rotation at all depths. In the Atlantic, the water driven northward along the American coast is blocked by the land, and is partly drained off by the easterly drift currents, partly sent downwards in a column separated into two parts, at least in certain seasons, by a bulging out of the cold Labrador current. Crossing towards the west coast of Europe, the easterly drift divides, a part escaping northward under regulation of the polar streams from the east of Greenland and Iceland, and a part banking up against the French and Spanish coasts and the north-west of Africa, as is shown by the "bottle charts" of the Prince of Monaco and M. Hautreux. The shape of the coast prevents all the water escaping laterally, and a part descends, carrying with it the efflux from the Mediterranean.

In the Pacific the effect is similar, subject to the difference that while the circulation is less energetic, it is also less inter-

fered with by the configuration of the land, and except off the coast of Central America, where the south-easterly drift is again "cornered," the effect of the earth's rotation becomes more apparent. The difference due to the Pacific being closed at its northern extremity is extremely striking.

H. N. DICKSON.

THE UNIVERSITY OF LONDON.

ON Monday the Duke of Devonshire introduced a Bill in the House of Lords to make further provision with respect to the University of London. In the course of a brief statement as to the circumstances which have led to the introduction of the Bill· the Duke of Devonshire explained that the Cowper Com, mission reported two years ago in favour of London University being made a teaching as well as an examining University, and recommended the appointment of a Statutory Commission to carry out the details of the scheme. It will be remembered that a Bill dealing with the question was introduced by Lord Playfair in the last Session of the late Parliament, but it was not proceeded with in consequence of the dissolution. His Lordship is reported by the *Times* to have said: "I believe that neither University College nor King's College is altogether satisfied with the scheme as sketched out in the Commissioners' report. But still more formidable opposition has manifested itself, not on the part of Convocation of London University as formally constituted, but on the part of a considerable body of members of Convocation residing for the most part in the provinces. This opposition, I believe, proceeds from an apprehension that under the proposed constitution of the University the teachers of the affiliated institutions and colleges will exercise a large and perhaps undue influence over the examinations of the University, and that students who have prosecuted their studies in independent colleges or privately will in future be placed at some disadvantage. The apprehension is that either the high standard which, it is admitted, has always been maintained by the London University will be lowered, or else that in the examinations arranged by the new body external students will compete on unfair terms as compared with students in the recognised teaching institutions. To meet objections of this kind we give in this Bill a somewhat wider discretion and larger powers to the proposed Statutory Commission than were proposed to be given in the Bill presented by Lord Playfair last year. While the Commissioners will be directed, as in the Bill of last year, to proceed upon the proposals of the late Royal Commission, they will also be directed to inquire into and have regard to the requirements of both the internal and external students. I trust that an opportunity will be afforded, by presenting this measure in a definite shape, to those who are concerned of ascertaining the real character of any opposition which may be offered to the proposed change in the constitution of the London University. Personally I am insensible to the motives which have actuated some graduates in offering considerable opposition to those proposals. After all it is the Senate of the London University which is charged with the duty, and on which rests the responsibility of watching over the interests and upholding the character of the University, and this Bill and the proposals of the Commission which it seeks to carry into effect have, I am assured, the warm approval of a large majority of the Senate of the University of London. This is a measure which practically has been recommended by two Royal Commissions, each of which was composed of men highly competent to pronounce an opinion on such a question as this. It is, I believe, supported by a very large majority of the most eminent scientific and educational authorities in the country, and it is, in my opinion, a very great anomaly, almost approaching to a scandal, that the great City of London should alone of all the great cities in the United Kingdom—and I believe I may add alone among the great cities of Europe—have remained up to this time without a teaching University. The experience during the last ten years of abortive attempts—which I have briefly recounted to your lordships—shows that almost insuperable difficulties exist to the establishment of any such teaching University in any other way than that which has been proposed by the late Royal Commission. It has been almost conclusively proved that the intervention of Parliament through the appointment of a Statutory Commission is necessary, and is the only means by which this desirable end can be effected." The Bill was then read a first time.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE French Senate has adopted the Bill for the establishment of district universities.

THE archæological library of the Ashmolean Museum at Oxford was struck by lightning during a severe storm on Tuesday, and the roof was set on fire, but fortunately the valuable books in the library were not damaged.

DR. J. NORMAN COLLIE, F.R.S., Assistant Professor of Chemistry at University College, London, has been appointed Professor of Chemistry in the Pharmaceutical Society's School of Pharmacy.

IN answer to a question put by Colonel Lockwood in the House of Commons, the Vice-President of the Council said, some nights ago, that the Teachers' Registration Bill could, as far as he could see, only be proceeded with this session if it were made entirely non-contentious.

LORD CROSS, Master of the Worshipful Company of Clothworkers, on Friday will lay the foundation-stone of a research laboratory in connection with the dyeing department of the Yorkshire College, Leeds. The expense of the new buildings, £15,000, is being borne by the Clothworkers' Company.

THE arrangements for the transfer of the right of patronage to the chair of Natural History in the University of Edinburgh, now exercised by the Crown, to the curators of patronage in the University, and the transfer of the right of patronage to the chair of Botany, now vested in the curators to the Crown, have been incorporated in a Bill, and the Bill has been introduced into the House of Lords by the Government.

AT the annual summer meeting of the Incorporated Association of Head Masters, which was opened on Friday last at Leicester, it was moved: "That to ensure the proper organisation of secondary education it is essential that, with the exception of non-local schools, every school or department of a school providing secondary education should be placed under a county authority administering secondary education." It was further agreed that the "local authority for secondary education should in no case administer a smaller area than that of an administrative county as defined by the Local Government Board."

REFERRING to the cost of education in Switzerland, Her Majesty's Secretary of Legation at Berne points out that it is much less than in England. In 1893 there were 8390 primary schools in Switzerland, with 469,800 children, and an average of 50 pupils per teacher, of whom there were 6290 masters and 3180 mistresses. The expenses of the cantons were, on an average, 50 francs (£2) per pupil, or 8 francs (6*s.* 8*d.*) per inhabitant. In the Polytechnic School of Zürich, to which the Federal Government makes an annual grant of £36,800, there are 720 pupils, of whom 309 are foreigners. Instruction is given in architecture, civil engineering, mechanics, chemistry, forestry, and training of teachers. The fees are about £8 10*s.* per pupil. There are commercial schools in six cantons, where the average expense to the pupil is £18 10*s.* per head. There are seven universities, with a total of 3742 male and 491 female students in theology, law, medicine, &c., among whom are many foreigners. There are, moreover, technical schools of all sorts for instruction in farming, dairy work, vine culture, &c., established throughout the country. In 1893, in the twenty-five cantons of the confederation, the expenses on account of education were, by the State, £660,200, and by the communes £839,960, making a total of £1,500,160, or an average of about 10*s.* per inhabitant. Under the heading of technical instruction £1,575,000 was spent in 1894.

THE Committee of Council on Education have decided to modify the existing rules for grants for instruction in science and in art, contained in the Science and Art Directory and the Minute of August 21, 1895, as follows, except as regards organised science schools and training colleges, to which these alterations do not apply:—In place of payments on the results of examination an attendance grant, except as stated below, will be made, on the certificate of the Committee of the

school, for each attendance of *at least* an hour's duration on the part of a student who has given not less than ten such attendances during the session. The minimum grant specified will be allowed if the inspector of the department reports that the teaching and equipment of the school are satisfactory, and that the class or classes are not too large for instruction by the staff of teachers. But these grants may be increased in any subject for efficiency up to the maximum specified; the efficiency being determined by the inspector's report and the success of the class in that subject at the May examination. The grants for science will be :—2*d.* to 6*d.* for each attendance in a night science class in the elementary stage, and 4*d.* to 1*s.* 4*d.* in the advanced stage; and for each attendance of 1½ hours' duration given to practical work in chemistry, physics, metallurgy, or biology, in a properly equipped laboratory, 3*d.* to 9*d.* in the elementary stage, and 6*d.* to 1*s.* 4*d.* in the advanced stage. The payments for attendance in a day science class will be at half the above rates. No student may be registered in the advanced stage of any subject until he has passed the examination of the department in the elementary stage, or has passed some corresponding examination which is considered by the department to sufficiently meet the requirements of the case. No student may be registered for more than two years for attendances in either the elementary or the advanced stage of any one subject. The grants will only be made if the student is of the industrial class as defined by the Science and Art Directory, and if the attendances for which the grant is claimed are such as can be legitimately registered under the rules. Grants for honours in the science subjects of the Department of Science and Art will continue on the same scale as at present.

An excellent survey of the systems of technical education in Austria, Germany, France, and Switzerland, compared with what is done in England and Ireland, is contained in a pamphlet entitled "Technical Education: a National Necessity, its Uses and Advantages," by Prof. Henry Corby, published by J. Mahony, Cork. Prof. Corby shows what technical education has accomplished on the continent, and points to the comparative neglect of it in England, the result being a loss of commercial supremacy. As to Ireland, technical education is almost unknown there. There is only one technical school of note, and that has been established within the past few years in Dublin. In Cork something has been done; but it is disjointed and fragmentary. However, it tends in the right direction, and we hope with Prof. Corby that it may yet prove to be the mosaic pavement on which will be raised a large and comprehensive technical school, which will be worthy of the commercial enterprise of the capital of the South of Ireland. It is suggested that good would come if Cork were raised to the dignity of a university city. Why not have a university for the South of Ireland in the capital of the South? At present, Prof. Corby points out, there are only two universities in Ireland, both located in Dublin, while Belgium, with a population almost exactly the same, has four universities; Scotland also has four, and in scientific Germany there are as many as thirty-one universities. To show what a thorough general and technical education can do for a country, it is only necessary to refer to Switzerland, which, though only about half the size of Ireland—and, as fully one-half of its soil is entirely unproductive, it may be regarded as only about one-fourth the size of Ireland—is able to maintain three million inhabitants, whilst the population of all Ireland is little more than four and a half millions. Prof. Corby describes what some continental nations have done for agriculture, and then he asks how can the smaller farmers of Ireland—many of them poor and half-educated—attempt to compete with such rivals? It has been urged that Ireland ought to have a Minister of Agriculture, but it is suggested that a Minister of General and Technical Education, who would give special attention to agriculture, would be better. If national teachers were trained at agricultural schools, and students were given practical instruction in agriculture, if chairs of Agriculture were established in all the higher colleges, and special lectures delivered in the auxiliary sciences, such as chemistry, zoology, botany, and mineralogy, then, thinks Prof. Corby, the hope might be entertained that the vast tracts of waste land in Ireland would be reclaimed, and a large scheme for reafforesting undertaken with every prospect of success. We trust that his admirable pamphlet will be the means of giving an impetus to the cause of technical education in Ireland.

SCIENTIFIC SERIALS.

The Reliquary and Illustrated Archæologist maintains its reputation for the beauty of its illustrations. In a late number (vol. ii. No. 2) an elegantly carved wooden Egyptian toilet-spoon of the eighteenth dynasty is reproduced in collotype.—The editor, J. Romilly Allen, has carefully studied the cup-and-ring sculptures of Ilkley in Yorkshire, and gives numerous illustrations of these still mysterious markings. All that we know about them is that they are religious symbols, and that they mostly belong to the Bronze Age, although cups only may possibly have been used at the end of the Neolithic period.—The much-discussed "Dwarfie Stone" of Hoy, Orkney, has been investigated by Mr. A. W. Johnston in a very thorough manner; he comes to the conclusion that it was originally a sepulchre with a stone door.

Internationales Archiv für Ethnographie (Heft 2, Bd. ix.)—The question of alleged native writing in Borneo is discussed by Mr. H. Ling Roth and Prof. H. Kern; inscriptions in one or two scripts are known, but there is no evidence that any form of writing was known to the Dyaks. Heer M. C. Schadee, in collaboration with Herr Schmeltz, has a communication on the ethnography of Western Borneo, which is illustrated in the characteristically excellent style of this journal. In the current number (Heft 3) Schmeltz continues his erudite notes on ethnographical objects from New Guinea. In a note entitled "Prudery in Scientific Matters," the same author states, on the authority of Prof. Brigham of Honolulu, that "the Government of New Zealand has not only prohibited the importation of the well-known phallic chalk idols from New Ireland, but in the Government Museum of Auckland all ithyphallic idols and figures have been castrated and mutilated." We hope that the Curator of the Museum will state how far this is or is not the case.

In the second number of the useful *Centralblatt für Anthropologie Ethnologie*, &c., is an article on the Necropolis of Novilara near Pesaro. According to Dr. P. Orsi the civilisation of Novilara was partly similar to and synchronous with that of Villanova. Three different culture streams have overlaid themselves, as it were, on the local substratum, and have contributed to give the Picinian culture its final form. One stream came from the north and west over the Apennines. The second came from the south, bringing with it the geometric vessels, which are wanting at Villanova, but appear in Istria; later this culture stream, which may be called the Greek one, brought Tarentinian silver coins and vases painted with black figures. The third stream is the Phœnician (partially also archaistic Greek) associated with figures of Astarte, glass beads and sepulchral steles with representations of naval war. The Necropolis belongs to the ninth to the seventh century B.C.

Bulletin de la Société des Naturalistes de Moscou, 1895, No. 4.—On adhesion of different metals to glass and other substances, by J. Weinberg, second article, in German.—On the winter flora of Nice, note by H. Trautschold.—Report on herborisation in the government of Smolensk, by A. Jaczewski.—The primary skeleton of the ventral fins of the Teleostei, by N. K. Kolzoff, in German, with illustrations; based on the study of thirty-six species.

SOCIETIES AND ACADEMIES.

London.

Royal Society, June 4.—"The Hysteresis of Iron in a Rotating Magnetic Field." By Francis G. Baily.

By deduction from the Weber-Maxwell-Ewing theory it has been surmised that the hysteresis in magnetic metals under the influence of a constant rotary magnetic field will be less than that in an alternating field in which the magnetising force passes through a zero value. It is supposed that residual magnetism is due to the combination of molecular magnets in stable magnetic arrangements, and that the energy dissipated in any magnetic change corresponds to the work done in breaking up these arrangements. Hence any movement of the molecular magnets during which the formation of new combinations is checked or prevented will take place with considerable reduction in the energy loss due to this cause. Such a condition is realised when the magnetic substance is subjected to a rotary magnetic

field of sufficient strength to force the molecules to maintain a direction parallel to that of the field. If hysteresis is due only to the formation of new combinations and not to mechanical restraint, then under these conditions it will vanish altogether.

Experiments were carried out to verify this deduction. A finely laminated cylinder of iron was suspended on its axis between the poles of a rotating electro-magnet, but was restrained from continuous rotation by a spring. On rotating the magnet, the armature was dragged round until the restoring force of the spring equalled the force due to hysteresis, and the value of the latter could be obtained from the observed deflexions. At first the value of the hysteresis was higher than that in an alternating field for corresponding inductions, but at an induction of about 16,000 in soft iron and 15,000 in hard steel the hysteresis reached a sharply defined maximum and rapidly diminished on more complete magnetisation, until at an induction of about 20,000 it became very small with every indication of disappearing altogether. Soft iron and hard steel gave very similar curves, and in both the curve of hysteresis-induction cut the curve obtained from the values in an alternating field at a point just before the maximum. The result fully bears out the deduction from the theory, and proves in addition that hysteresis is not sensibly due to anything of the nature of mechanical restraint of the molecules. The form of the curve also gives clear indications of the three stages of molecular movement, the first stage giving a slowly rising curve, the second a straight rapid rise, and the third a straight and much more rapid descent.

Further experiments were carried out on the effect of speed of rotation. In an alternating field the speed of reversal has been shown to be without sensible effect on the hysteresis, and theory points to this result as a natural deduction. From an extremely slow speed up to seventy revolutions per second no definite change was found in the value of the hysteresis. At the same time several small modifications were noted, produced by rapid variations in the speed of rotation or magnetising force. The effect lasted through many revolutions, but ultimately the same steady condition was arrived at. At and near the maximum value the hysteresis was very variable. The effects were much more marked in soft iron than in hard steel, as would be anticipated from the theory of their constitution.

June 11.—"The Relation between the Refraction of the Elements and their Chemical Equivalents." By Dr. J. H. Gladstone, F.R.S.

This paper is intended to give a preliminary account of some recent investigations into the specific refraction of the elements. The first part contains the atomic weights, with the specific and atomic refractions of fifty-five of the elements.

The specific refraction cannot claim a constancy equal to that of the atomic weight. Several of the elements exhibit two or more values, besides many smaller variations scarcely, if at all, beyond the limits of experimental error, which depend upon differences of physical condition or chemical combination.

The second part deals with a law previously suggested by the author, namely, that the "specific refractive energy of a metal is inversely as the square root of its combining proportion." The product of these two quantities as determined from their compounds is found to be for 5 univalent metals about 1·3, for 10 bivalent metals about 0·99, for 7 trivalents about 1·01, for 6 quadrivalents about 1·06, and for one quinquivalent 0·98.

The observations show: First, that the metals which have the same valency, have the same, or nearly the same, constant of refraction for equivalent weights. Secondly, that the constants of the bivalent, trivalent, quadrivalent, and apparently quinquivalent groups are practically the same, ranging about 1·01. Thirdly, that when a metal combines in a proportion that indicates a lower valency than that ordinarily assigned to it, its constant is somewhat elevated.

The relation involved is not between the optical property and the atomic weight, but between it and the electro-chemical equivalent.

It is proposed to give this product the descriptive name, "Refractive constant of equivalent weights." It may be represented by—

$$SE^{\frac{1}{2}} = \text{constant, or by } S^2E = \text{constant},$$

where S is the specific refraction, and E the chemical equivalent of the metal.

The Lorenz expression for S may be equally used if preferred.

This is suggested as a first approximation to a law, which holds good, however, only for the metallic elements, and that when they are electro-positive radicals.

"The Effects of a strong Magnetic Field upon Electric Discharges in Vacuo." By A. A. C. Swinton.

This paper deals with some effects of a strong magnetic field upon electric discharges in vacuo.

A pear-shaped Crookes' tube was suspended with the kathode terminal uppermost above the pole of a very powerful electro-magnet.

When the magnet was not excited the walls of the tube showed everywhere green fluorescence, which was especially strong over the rounded end of the tube opposite the kathode. When the magnet was magnetised, the whole appearance of the discharge was found to alter immediately to what is shown in the illustration (Fig. 1). Excepting for a little near the kathode and

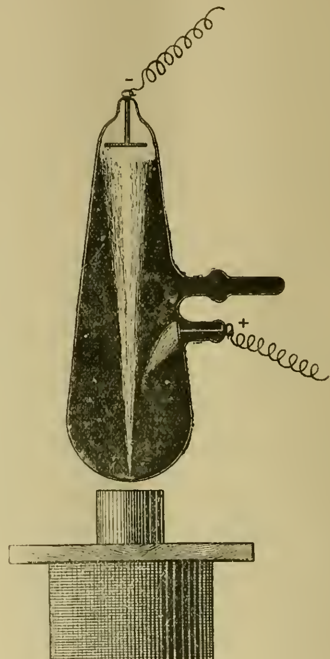

FIG. 1.

a very bright spot at the bottom immediately over the centre of the magnet pole, all the green fluorescence disappeared, while extending from near the kathode to the bright spot at the bottom of the tube a very bright cone of blue luminescence made its appearance.

When under these conditions the tube was moved sideways, the bright spot at the apex of the cone and the cone itself moved, the spot and apex always maintaining a position exactly over the centre of the magnet pole.

At the same time, while the magnet was excited, the internal resistance of the tube as measured by an alternative spark gap was found to be very greatly diminished.

On demagnetising the magnet the appearance of the discharge and the resistance of the tube immediately reverted to what they had been previously. The effect was quite independent of the polarity of magnet pole, and when the position of the tube was

reversed, so that the kathode was next the magnet, the excitation of the magnet reduced the resistance of the tube as formerly, the green fluorescence at the same time disappearing; but the blue luminescence, instead of being concentrated into a cone, was diffused throughout the whole interior of the tube.

[Since the above paper was written, further experiments have revealed the following additional facts.

With a tube of the form shown, exhausted to an extent that gave X-rays plentifully under ordinary conditions, and supported over an electro-magnet as shown in Fig. 1, the X-rays disappeared as soon as the magnet was excited, but reappeared the moment the magnet was demagnetised.

With another tube of similar form but furnished with an inclined platinum plate forming the anode placed near the bottom of the tube, similar results were obtained. This tube being kept on the pump was further exhausted to a degree that allowed the electric discharge to pass with difficulty when the magnet was not excited, and under these conditions gave X-rays of a character that penetrated the bones of the hand almost as easily as the flesh with but little contrast. With this exhaustion the excitation of the magnet not only caused the kathode rays to focus on the platinum, thus giving sharper shadows, but at the same time had precisely the same effect as lowering the vacuum in so far as the moment the magnet was excited the X-rays became more plentiful, and became of such a character as to penetrate the flesh with much greater ease than the bone, so that the contrast between bone and flesh was exceedingly marked. A photograph of the hand taken with one minute's exposure with the tube in this condition, and with the magnet excited, though considerably over-exposed, proved to be a very good one. Further investigations are in progress, but the application of a strong magnetic field in the manner described, gives promise of having considerable practical utility, not only in so far as it facilitates the accurate focusing of the rays proceeding from a flat kathode upon any desired point of the platinum anode, but also and more especially because by employing a high exhaustion and by varying the intensity of the magnetic field, it is possible at will to arrive with ease at the exact conditions requisite to produce a maximum of X-rays of exactly the penetrative character that may be best for any given purpose, a result which hitherto has been difficult of attainment.—A. A. C. S., July 7.]

June 18.—"A Magnetic Detector of Electrical Waves, and some of its applications." By E. Rutherford, 1851 Exhibition Science Scholar, New Zealand University, Trinity College, Cambridge.

The effect of Leyden jar discharges on the magnetisation of steel needles is investigated, and it is shown that the partial demagnetisation of strongly magnetised steel needles offers a simple and convenient means for detecting and comparing currents of great rapidity of alternation.

The partial demagnetisation of a collection of fine steel wires, insulated from each other, and over which is wound a small solenoid in series with the receiving wires, was found to be a sensitive means of detecting electrical waves at long distances from the vibrator. A small but quite marked effect was obtained at a distance of half a mile from the vibrator.

A fine steel wire detector was found to be of the same order of sensitiveness as a bolometer for investigating waves along wires.

This detector has the property of distinguishing between the first and second half oscillations of a Leyden jar discharge, and may be readily used for determining the damping of oscillations. The absorption of energy of spark gaps of different lengths is investigated.

The resistances of iron wires for high frequency discharges are quantitatively determined. The permeability of the different specimens is deduced, and it is shown that the calculated value of the permeability varies greatly with the diameter of the wire and the intensity of the discharge.

A method of experimentally determining the period of oscillation of a discharge is based on the division of a rapidly alternating current in a multiple circuit, one arm of which is composed of a standard inductance, and the other of a variable electrolytic resistance.

PARIS.

Academy of Sciences, June 29.—M. A. Cornu in the chair.—Some properties of the secondary roots of prime numbers, by M. de Jonquières.—Formulæ for the coefficient of internal friction in gradually varied flow of liquids, by M. J. Boussinesq.—Remarks by M. Appell on presentation of his work on "The principles of the theory of elliptic functions and their applications."—M. Albert Goudny announced the death of Sir Joseph Prestwich, correspondent of the Academy in the Section of Mineralogy.—M. Bakhuyzen was elected a correspondent for the Section of Astronomy.—Report on a memoir of M. Bazin, entitled "New experiments on the distribution of velocities in pipes."—Control of the results obtained by the dynamometric pedal of the bicycle, by M. Bouny. Experiments in which the work done was measured at the same time on the brake and by the dynamometric pedal, showed that about 95 per cent. of the work exerted on the pedals was shown by the brake, the remaining 5 per cent. being absorbed by the friction of the axes of the pedals, the chain, and the axis joining the cranks.—Actinometric experiments made on Mont Blanc with a view to determine the solar constant, by M. J. Vallot. Simultaneous observations were made at Chamounix and at the summit of Mont Blanc. Two types of instrument were used, the absolute actinometer of M. Violle, and the mercury actinometer of M. Crova. Extremely concordant results were obtained, giving as a mean value 1·70 for the solar constant.—On rays when $\lambda = 0$, by M. C. Maltézos.—On the spectrum of phosphorus in fused salts and in certain metallurgical products, by M. A. de Gramont. Fused phosphates submitted to the action of a condensed spark, give a fine spectrum of the lines of phosphorus of greater clearness and intensity than the spectrum given by a Plücker tube containing phosphorus. The same method showed easily the presence of phosphorus in alloys, as little as 2 per cent. being readily recognised by the characteristic triplet in the red.—On the blue nitrodisulphonic acid and some of its salts, by M. Paul Sabatier.—Action of iodine upon stannous chloride, by M. V. Thomas. Mixed addition products, similar to those obtained with bromine, were not found, the reaction taking a different direction according to the equation

$$3SnCl_2 + 7I_2 = 3SnI_4 + 2ICl_3.$$

Thermal researches on the uranium compounds, by M. J. Aloy. The heats of solution and formation of some of the commoner uranyl salts.—New method for the preparation of aromatic aldehydes, by M. L. Bouveault. The hydrocarbons are converted into glyoxylic acids by means of ethoxalyl chloride in presence of aluminium chloride, and these heated with aniline give nearly quantitative yields of phenylimides, the condensation to the phenylimido-acid and elimination of CO_2 from the latter proceeding simultaneously. A good yield of the corresponding aldehyde is obtained on hydrolysing the phenylimide by boiling with dilute sulphuric acid. The aldehyde group has in this way been introduced into toluenes m-xylene, cymene, anisol, di-methyl ether of resorcinol, and of di-methyl-hydroquinol.—Researches on the chlorination of gallic acid. Formation of dichlorogallic acid and of trichloropyrogallol, by M. A. Biétrix.—Crystallographic properties of benzylidene, methylsalicidene, ethylsalicidene, and anisol camphors, by M. J. Minguin.—On isaric acid, a new unsaturated fatty acid, by M. A. Hébert.—Digestive apparatus of *Brachytrypes membranaceous*, by M. Bordas. This has many points of resemblance with the *Gryllotalpa*, but differs from this species by the atrophy of the œsophagus, the reduction of the intestinal appendices, and especially by the great length and numerous circumvolutions of the intestine proper.—On a coloration of hepatic origin in the oyster, by M. J. Chatin.—Petrographical study of the meteoric stone that fell at Madrid, February 10, 1896, by M. Gredilla y Gauna. In the metallic portion schreibersite, ivoilite, and chromite were recognisable, whilst the stony portion contained the minerals peridote, enstatite, augite, plagioclase-oligoclase felspar, and olivine.—The grotto of Spelugues, by M. E. Rivière. This cave was discovered during the construction of a railway near Monte-Carlo, and contained human bones, apparently from nine individuals. Other bones represented the remains of animals resembling fox, hare, and sheep. The conclusion is drawn that the race of men represented by these remains lived in the Neolithic period, and are quite distinct from the race whose remains have been found in the cave of Mentone.—On an electric variation determined in the acoustic nerve when excited by sound, by MM. H. Beauregard and E. Dupuy.—Action of diverse substances upon the movements of the stomach, and the ennervation of that organ, by M. F. Battelli. Of all the substances examined, muscarine, pilocarpine, and physostigmine exercised the most energetic effect upon the movements of the stomach. Less energetic are nicotine and other alkaloids, alcohol, and peptone; whilst purgatives, strychnine, and pepsine were without action.—On specific heats, by M. J. Taupin.

PHILADELPHIA.

Academy of Natural Sciences, June 9.—Papers under the following titles were presented for publication:—"Contributions to a knowledge of the Hymenoptera of Brazil," by Wm. J. Fox; "The Correct Position of the Aperture of Planorbis," by Frank C. Baker; "The Mesenteries of the Lacerti ia," by E. D. Cope; "Revision of the Slugs of North America—Ariolimax and Aphallarion," by Henry A. Pilsbry and E. G. Vanatta.—Dr. Harrison Allen made a communication on forms considered specific, but which were merely instances of arrested development. He referred in illustration to certain species of *Vespertilio*, claiming that *Lucifugus* is merely an arrested form of *Gryphus*, the species *Albescens* also being based on similar characters. He had applied the term pædomorphism to the condition which had been worked out, he believed, only among the bats, and by himself. He held that the specific names of such forms were not valid, and should be dropped. Dr. George H. Horn stated that many such instances of arrested development were found among insects. He referred to the dimorphic males of *Eupsalis minuta*, a rhyncophorous beetle on which a French writer had founded three species. The egg-depositing habits of the female, and the assistance rendered when necessary by the male, were commented on.

June 8 (Botanical Section).—A paper was read from Mr. Thomas Meehan on *Erigeron strigosus*. A tendency of the ray florets to become discoidal, together with an acceleration from the lingulate to the discoid condition, was noted. The hermaphrodite state of the flower is not established until the tubular condition becomes permanent.—Dr. Ida A. Keller recorded the fact that if a cold alcoholic solution of chlorophyl be treated with benzol, the chlorophyl will be extracted and float as a green film on the surface of the liquid.

NEW OUTH WALES.

Linnean Society, May 27.—Mr. Henry Deane, President, in the chair.—Observations on Peripatus, by Thomas Steel. In this paper was embodied an extended series of observations on the habits and characteristics, food supply and life-history, with remarks on the individual range of colours, and relative proportions of the sexes, based on the examination of numerous living specimens of various ages kept under continuous observation for more than a year.—Descriptions of new Australian Fungi, (No. 1), by D. McAlpine.—Description of a new species of *Astralium* from New Britain, by C. Hedley and Dr. Arthur Willey. *A. moniliferum* (n. sp.), allied to the Japanese *A. triumphans*; dredged in 30 to 40 fathoms on a shelly bottom.—On a rare variation in the shell of *Pterocera lambis* (Linn.), by Dr. Arthur Willey. A series of sixty-seven specimens of this common tropical species from New Britain and the Eastern Archipelago of New Guinea has been examined. Numerous instances of substantive variation were met with, the more striking of which relate to the curvature of the digitations, their length, the intervals between them, and the extent to which the apical whorls of the shell are involved in, concealed by, or fused with the posterior digitation. There is also much variation as to the stage of growth at which the deposition of callus on the outer lip of the shell takes place.

AMSTERDAM.

Royal Academy of Sciences, May 30.—Prof. van de Sande Bakhuyzen in the chair.—Prof. Hubrecht gave a description of the embryonic vesicle of *Tarsius spectrum*, and pointed out its close resemblance to that of man and monkeys. From this and from the placentation the author concluded that the order of Primates should henceforth embrace only the Hominidæ, the Siniæ, Tarsius, and the fossil Anaptomorphus. He was, moreover, disinclined to admit the possibility of deriving the placental arrangements, and the peculiarities of the clastocyst of the Primates from what is presented by the *Lemures*. The Primates should be derived from certain unknown insectivorous mammals of the Mesozoic period, of which the recent Erinaceus and Gymnura might perhaps prove to be the least distant relatives.—Prof. Pekelharing described a new method of preparing pepsin.—Prof. Schoute read a paper on the area of parabolæ of higher order, and, on behalf of Prof. Holleman, a communication to the effect that already some months ago he obtained the isophenylnitromethane recently described by Hantzsch and Schulze, and that his results were identical with those arrived at by these chemists. Mr. Holleman has also studied the reaction between benzoylchloride and the sodium compound of phenylnitromethane, and in doing so obtained dibenzohydroxamic acid.—Prof. Franchimont described isomers of neutral nitramines. They were obtained by Mr. van Erp both from the potassium compounds and the silver compounds of the acid nitramines; in the first case as a secondary product, in the second case as the principal product. Their boiling points and their specific gravity are lower than those of the nitramines; moreover, they are strongly affected by sulphuric acid, with the formation of gases, which is not the case with nitramines. By decomposition with alkali solutions, butylmethylnitramine yielded butylamine, while the isomer produced butyl alcohol; so that it seems as if in the first case butyl is united with nitrogen, in the second with oxygen. By the action of methylnitramine potassium upon allylbromide, Dr. H. Umbgrove obtained, besides allylmethylnitramine, also an isomer with a lower boiling-point, and acting violently upon sulphuric acid. A similar isomer seems also to be produced, in addition to ordinary dimethylnitramine, when methylnitramine is heated by itself, while nitrous oxide escapes. When heated with β-naphthol nitrogen escapes, and β-naphtholmethyl ether is formed, besides colouring matters.—Prof. Kamerlingh Onnes presented a communication concerning the measurement of low temperatures, and (on behalf of Mr. E. van Everdingen, jun.) (1) remarks on the method of observing Hall's effect; (2) measurements on the dissymmetry of Hall's effect in bismuth, and on the average Hall-effect in bismuth and antimony, carried out in the Leyden physical laboratory.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Skertchly's Physical Geography, revised edition (Murby).—Practical Radiography: H. S. Ward ("Photogram," Ltd.).—Beginner's Guide to Photography, 6th edition (Perken).—The Universal Law of the Affinities of Atoms: J. H. Loader (Chapman).

PAMPHLETS.—Absolute Oder relative Bewegung?: Dr. B. and I. Friedlaender (Berlin, Simion).—The Position of Argon and Helium among the Elements: Prof. W. Ramsay (Frowde).

SERIALS.—Lloyd's Natural History. Butterflies: W. F. Kirby. Part 2 (Lloyd).—Scribner's Magazine, July (Low).—Humanitarian, July (Hutchinson).—Journal of the Royal Agricultural Society of England, Vol. vii Part 2, No. 26 (Murray).—A Monograph of the Land and Fresh-water Mollusca of the British Isles: J. W. Taylor, Part 3 (Leeds, Taylor)—Bulletin de la Société de Géographie, 4e Trimestre, 1895 (Paris).—Astrophysical Journal, April and June (Chicago).—Fortnightly Review, July (Chapman).—Sitzungsberichte der Physikalisch-Medicinischen Societät in Erlangen, 27 Heft. 95 (Erlangen).—Proceedings of the Society for Psychical Research, June (K. Paul).—Westminster Review, July (Warne).—Geographical Journal, July (Stanford).—Annals of Scottish Natural History, July (Edinburgh, Douglas).—Mind, July (Williams).

THURSDAY, JULY 16, 1896.

THE ZOOLOGICAL RESULTS OF THE HORN SCIENTIFIC EXPEDITION TO CENTRAL AUSTRALIA.

Report on the Work of the Horn Scientific Expedition to Central Australia. Part ii. Zoology. 4to, pp. 431, plates 29. (London: Dulau. Melbourne: Melville, 1896.)

IT is becoming quite the fashion, we are glad to say, nowadays for private individuals who possess the necessary means, to send out scientific expeditions at their own cost. This laudable practice has long been prevalent in the United States, where, many years ago, the expense of Louis Agassiz's journey to South America was borne by a friend interested in science. In England we have at present the "Jackson-Harmsworth Expedition" to Franz-Josef Land generously sustained by Mr. Harmsworth; and other examples of similar munificence are well known. Our more advanced colonies are now following these excellent precedents, and the entire cost of the successful expedition into Central Australia, of which some of the results are now before us, has been borne by Mr. William Austin Horn, of Adelaide, who, we believe, also devised the plan of it. But not only was the plan Australian and the means to carry it out provided in Australia, but the members of the expedition were Australian, the results have been worked out in Australia by Australians, and the reports on the results printed, illustrated, and published in Australia. Australia may therefore be well proud of the Horn Expedition, and thankful to Mr. Horn for having projected it and carried it out.

It having been suggested by scientific men that in the last geological epoch, when the rest of the continent was submerged, the MacDonnell Ranges in Central Australia existed as an island, and that, consequently, older forms of life might still be found in their more inaccessible parts, Mr. Horn determined to try and solve this question in a practical manner. His proposal was received with great favour all over Australia, and Mr. Horn was fortunate enough to secure the services of Prof. Spencer of Melbourne, Mr. Watt of Sydney, and Prof. Tate and Dr. Stirling of Adelaide to carry it out. Mr. Winnecke was selected as surveyor and meteorologist. The party, completely equipped and accompanied by camel-drivers, collectors, prospectors, and others—sixteen in all, with twenty-six camels and two horses—left Oodnadatta, the northern terminus of the railway from Adelaide, on May 6, 1894. Mr. Horn himself escorted them to a point 1000 miles north of Adelaide. Here he left them to proceed into the recesses of the "Eremian region," where they devoted about three months to their explorations. The greater part of this time was spent in what is termed the "Larapintine" district, where the MacDonnell Ranges run up to an altitude of 5000 feet, and are drained by the Finke River, of which the native name is the Larapinta. We will now proceed to examine the results arrived at from the study of the zoological collections made by the expedition in this district.

The volume before us contains articles on the Mammals, Amphibians and Crustaceans, by Prof. Spencer; on the Birds, by Mr. North; on the Reptiles, by Messrs. Lucas and Frost; on the Fishes, by Mr. Zietz; and on the Molluscs, by Prof. Tate. Various leading groups of Insects are reported on by Mr. Lower, the Rev. T. Blackburn, Mr. Tepper, Mr. Sloane, and Mr. Froggatt. Mr. H. R. Hogg writes on the Spiders, and Mr. Waite specially on the difficult group of Mice (Muridæ). There are some additions made in an appendix.

From Prof. Spencer's report on the Mammals we learn that examples of twenty-six species, representing all the five orders of Mammals met with elsewhere in Australia, were secured, of which the Marsupials were naturally the most numerous, twelve of the species being referable to this group. Four of these are assigned to new specific forms, which Prof. Spencer has named *Phascologale macdonnellensis*, *Sminthopsis larapinta*, *S. psammophilus*, and *Dasyuroides byrnei*. The so-called "Marsupial Mole" (*Notoryctes typhlops*) is the single representative of the only family of Marsupials confined exclusively to the "Eremian region." This little animal is still extremely rare and difficult to obtain, but more than forty specimens have passed through Prof. Spencer's hands, and some interesting details are given about it. Dr. Stirling, its original discoverer, and Prof. Spencer are now engaged upon an investigation of its teeth, fur, and reproductive organs.

As regards the latter, Prof. Spencer has already come to the conclusion that *Notoryctes* is "merely a Marsupial modified so as to adopt the burrowing habits," and is "in no manner whatever an intermediate form between Monotremes and Marsupials."

The bird skins obtained during the Horn Expedition by Mr. G. A. Keartland are reported upon by Mr. North, the ornithologist of the Australian Museum, Sydney. They are referred to seventy-eight species, amongst which are five novelties already described in *The Ibis* for 1895. Mr. Keartland's useful field-notes are given, as also his remarks on twenty-two other species observed, but of which no specimens were obtained. As a rule, the species belong to well-known Australian genera. One of the most remarkable is the Alexandrine Parrakeet (*Polytelis alexandræ*), described by Gould in 1863, of which little, however, was known until recently. This beautiful bird appears to be a characteristic inhabitant of the Eremian district, and was met with in abundance at Glen Edith. Mr. North has made a new genus of it—*Spathopterus*—which appears to be quite unnecessary. We may add that living specimens of it, of both sexes, are now to be seen in the Zoological Society's parrot-house.

The Reptiles of the Horn Expedition consist of Lizards and Snakes. The former are referred by Messrs. Lucas and Frost to forty species, amongst which, however, are counted some specimens obtained by Prof. Spencer [during a second visit to the same district in the winter of 1895. In the dry and hot interior of Australia, Lacertine life is, as was to be expected, abundant, both in individuals and in species, and eight forms are described by the authors as new and characteristic of the Eremian district. The Geckos, Agamids, and Skinks are the prevailing families here, as in the rest of Australia. Besides these no less than six species of

Varanus were met with, of which two are believed to be previously unrecognised. The remarkably ugly *Moloch horridus* was met with "in the open, during the day," throughout the expedition. The Snakes were not so numerous as the Lizards, but *Hornea pulchella*, a new genus and species of Elapidæ, was amongst the discoveries.

It would hardly be supposed that Central Australia would be a likely place for Amphibians, but wherever there were water-holes frogs were found in fair numbers, and Prof. Spencer gives us some very interesting remarks on them. Almost all of them belonged to two species—*Hyla rubella* and *Limnodynastes ornatus*. On visiting Charlotte Waters immediately after a heavy rainfall, Prof. Spencer found the "creeks and clay-pans swarming with frogs." As the waters dry up, the frogs disappear in their burrows, and remain hidden until rain comes again. Certain species of them (*Chiroleptes platycephalus* and others) gorge themselves with water before they go into their retreats, and in times of drought the natives dig them out and secure water enough from their bodies to satisfy thirst. Prof. Spencer gives a figure (Pl. xiv., Fig. 9) of a specimen of the above-named species with its "body swollen out with water."

As the frogs, so the fishes of the Eremian district hide themselves in the deeper water-holes, but they are not known to burrow. Examples of seven species were obtained, five of which, representing four genera, are new to science, and are described as such by Mr. Zietz.

Prof. Tate, one of the members of the expedition, himself describes the Mollusca. Before the advent of the party, the published information respecting the land-shells of this region was limited to three species, which number is now increased to twenty-five—nearly all of them new to science. The facies of this part of the Fauna approximates rather to that of West Australia, than to any other part of the continent.

> "The limited number of genera represented, together with the facts of their distribution, seem to indicate a primitive population which has been maintained in isolation by climatic and geological changes."

One genus (the Central-Australian Mollusca) was previously known only from New Caledonia. Mr. Hedley adds to Prof. Tate's article notes on the anatomical structure of some of the species.

For an account of the Crustacea of the Horn Expedition, we are again indebted to Prof. Spencer, who remarks that the rate of growth of some of the species must be very great. Not more than two weeks after rain had first fallen, and probably in only a few days, numberless specimens of an *Apus*, measuring from two to three inches in length, were swimming about in the water-holes, whereas before the rainfall not a single one could be found. Ten species of Crustacea in all were met with, *Estheria packardi* being the most widely distributed; whilst two (*Limnadopsis squirei* and *L. tatei*) are, so far as is yet known, confined to the central region.

We need not go deeply into the various groups of insects which are the subjects of most of the remaining pages of the volume. Butterflies are rare in Central Australia, and examples of only five (already known) species were met with, and of moths specimens of only about fifteen species were captured. On the other hand, 800 specimens of Coleoptera, representing 145 species, were obtained, and of these sixty-two are new, and four of them belong to new genera. The Coleoptera were worked out by the Rev. T. Blackburn, of the South Australian Museum, except the Carabidæ, which Mr. Sloane undertook. Mr. J. G. O. Tepper informs us that the Orthoptera brought back by the expedition present few novelties, but that the knowledge acquired as to the distribution of the species is valuable. As regards the Formicidæ, a special essay is contributed by Mr. Froggatt on the Honey-ants. It is perhaps little known, except amongst professed entomologists, that certain species of this group have adopted the curious plan of "turning some of their fellows into animated honey-pots." Instead of placing honey in a comb as the busy bees do, the ants select a certain number of workers, and disgorge the honey obtained from the Eucalypti (on which it is deposited by Coccidæ and other insects) into the throats of their victims. The process being continually repeated, causes the stomachs of these workers to be distended to an enormous size. This extraordinary habit was first discovered in the case of certain ants in Mexico, and subsequently shown by Mr. M'Cook to prevail also in Colorado. It has been found to exist in Australia also, and Mr. Froggatt describes and figures three ants of the genus *Camponotus* that pursue this remarkable practice. The enormous size of the abdomen thus acquired by the unfortunate worker is shown in the central figure of Plate xxvii. These ants are a favourite food of the hungry native.

To sum up, we may repeat that this volume, which is well printed on good paper and excellently illustrated, does the greatest credit to Australia and to its enterprising citizens. They may well be pleased with Mr. Horn, who has not only planned and executed this important piece of work, but has also exerted himself so successfully on a point that is too often neglected in such undertakings — that is, on having the results thoroughly well worked out, and thus made known to science all over the world.

THE WATER SUPPLY OF NEW YORK.

The Water Supply of the City of New York, 1658–1895. By Edward Wegmann, C.E. (New York: J. Wiley and Sons. London: Chapman and Hall, 1896.)

THIS work consists of a quarto volume of nearly 200 pages, with appendices and 148 plates, in addition to seventy-three figures in the text.

It was not until the year 1842 that the citizens of New York were able to celebrate the completion of their first water-works of importance. The works then constructed soon proved inadequate to the supply, and have had to be supplemented from time to time from other sources.

In view of the agitation which is now going on for improving the water supply of London, the particulars given in this book, of the various steps which have been taken for providing an adequate supply to the City of New York, are of considerable interest.

In 1875, the then source of supply being found in-

sufficient, the Department of Public Works submitted plans for new water-works. The reports on these plans were submitted by the Mayor to the Legislature. The Senate requested the Mayor to nominate five citizens who, in conjunction with himself, were to report on the best scheme to be adopted. After holding thirty-three public meetings, at which eminent engineers and citizens expressed their views with reference to the proposed works, a scheme was approved and adopted, the source of supply being the Croton River, from which the water hitherto in use has been obtained. They also advised that the works should be entrusted to "an unprejudiced Commission selected from the best citizens of the city." The Committee drew up a draft Bill embodying these recommendations, which formed the basis of "An Act to provide new reservoirs, dams, and a new aqueduct with the appurtenances thereto for the purpose of supplying the City of New York with an increased supply of pure and wholesome water," which was passed by the Legislature in 1883. An "Aqueduct Commission" was appointed, consisting of the Mayor, the Comptroller, the Commissioner of Public Works *ex officio*, and three citizens, the salary of each of the Commissioners being fixed at 8000 dollars (£1680) a year. The works carried out will be referred to later on.

The book under notice, which has been prepared by Mr. Wegmann, one of the engineers of the Water Commission, gives the history of the water-works of the City of New York from the sinking of the first public well in 1658 to the present time, and full technical details of the new works. This description cannot fail to be of interest to engineers engaged in water supply, and the great number of illustrations of the details of the construction, as showing the difference between English and American practice, are instructive, and may even give hints for the adoption of new methods of carrying out works of a similar character in this country.

Within about 300 years the population of New York has increased a thousand-fold, the number of inhabitants in 1664 being 1500, and now 1,515,301.

The first attempt at a public water supply was in 1658, when "the Burgomasters resolved to communicate with the Herr General relative to having a public well made in Heere Street," and subsequently six public wells were sunk. As the population increased, the well-water became polluted, and the inhabitants had to send to springs situated on the outskirts of the city for pure water. One of the most noted of these springs was known as the "Old Tea-water Pump," which is thus described in the diary of a traveller in 1748.

"There is no good water in the town itself, but at a little distance there is a large spring of good water, which the inhabitants take for their tea and for the uses of the kitchen. Those, however, who are less delicate on this point, make use of the water from the wells in the town, though it be very bad."

When the population had increased to 22,000, the Common Council of the city accepted a proposal of an English engineer, Christopher Colles, to construct a reservoir on Manhattan Island for supplying the city with water. The water was pumped up by one of Newcomen's atmospheric engines, and distributed through mains consisting of hollow logs. Owing, however, to the insufficiency of the supply, and the confusion caused by the Revolution, this enterprise became abandoned. The next scheme for supplying the city with water was due to an Act of the Legislature, which, under the guise of incorporating a company for supplying the city with pure water, really was for the purpose of establishing the Manhattan Bank, the company being authorised by the Act to raise a large amount of capital, and employ it "in any other moneyed transactions or operations not inconsistent with the constitution and laws of the State." Only enough was done in introducing water to maintain the charter, the real object of the incorporation being the formation of the bank, to which there had been very strong opposition. For several years after this the water supply of the city remained in a very unsatisfactory state, and numerous schemes for providing a better supply were brought forward. From documents published in 1832 it appears that the quality of the water then used did not conduce to temperance, as one of the arguments used in favour of a new supply was: "By thus supplying the inhabitants with fine pure rock water, it will remove the popular pretext for using alcohol to correct the impurities of the water now in general use, and will be the most effectual means of promoting the great and noble cause of temperance in this city." The temperance cause seemed to occupy a considerable amount of public attention at this time, as in one of the contracts made for the construction of the new water-works was a clause to the effect that the contractor should not sell or allow to be sold any ardent spirits to their workmen, or to any person near the line of the works.

In 1834 an Act was passed forming a permanent Water Commission, and providing for the raising of £325,000 for constructing water-works. The Croton River was decided on as the source of supply. This river is situated thirty-three miles from the city. The water-shed above the dam has a ridge line of 101 miles, and an area of 532 square miles. Within this area are contained thirty-one natural lakes and ponds. The length of the river is thirty-nine miles, and its minimum flow above the dam 33,804,000 gallons. The average rainfall is 42·68 inches, the minimum being 38·52 inches.

The first, or "Fountain," reservoir was formed by constructing a dam across the river six miles above its mouth. The lake is four miles long, and has a width of about a quarter of a mile. Its area is 400 acres, and storage capacity 600 million gallons. The water was conveyed to the city by a masonry aqueduct a distance of thirty-three miles. The masonry conduit is 7 feet 6 inches in diameter with upright sides, and has an area of 53·34 feet. When the water was first admitted in 1842, a boat containing four persons was placed in the current, and arrived almost simultaneously with the water at the Harlem River, the velocity of the current being at the rate of one mile in forty minutes. The mean fall of the invert is at the rate of 0·6 feet per mile. The aqueduct is capable of discharging ninety-five million gallons in twenty-four hours. The distributing reservoir, situated three miles from the city, was constructed almost entirely above ground, by means of walls thirty-six to forty-nine feet above the surface. This reservoir is 420 feet square, and has a depth of water of thirty-six feet, the capacity being twenty-four million gallons. After the works became in

full operation, no restriction being placed on the quantity used, the daily consumption amounted to seventy-eight gallons per head of the whole population, or ninety gallons for each water consumer.

From time to time the works have had to be enlarged and additional reservoirs built, until in 1875 it was determined to build a second aqueduct connected with a new reservoir to hold 1900 millions of gallons.

The new aqueduct, including a short length of pipe line, is thirty-four miles long, twenty-nine miles of which are in tunnel through gneiss rock. This aqueduct is lined throughout with masonry. The standard shape, where not under pressure, is of horseshoe section with a diameter of fourteen feet, the sectional area being equal to a circular masonry culvert having an internal diameter of fourteen feet. The available head is 33·70 feet, which is absorbed in overcoming friction through the conduit and pipes. The grade is at the rate of 0·7 feet per mile, and the velocity of the flowing water 3·27 feet per second. It is capable of discharging 300 millions of gallons in twenty-four hours.

The "Cornell" reservoir, now under construction, will contain when completed 32,000 million gallons. The central masonry dam is 600 feet long, with an earthen continuation of the same length. The maximum height of the masonry dam is 260 feet, the height above the river-bed being 159 feet, the top being 10 feet above the water-line. It is to be 18 feet wide at the top, and 185 feet at the base.

The total capacity of the conduits now supplying the city, which has a population at the present time of one and a half millions, is 425 millions of gallons. The total storage capacity of the reservoir is 75,000 millions of gallons, equal to a minimum supply in the driest years of 280 millions of gallons.

Mr. Wegmann's book is almost entirely of an historical and descriptive character, and is confined entirely to the works carried out for the water supply of New York. The details of these various works are, however, so copiously illustrated that they give the book an eminently practical character, which renders it of value to any engineer engaged in water-works construction.

A NEW CHEMICAL DICTIONARY.

A Dictionary of Chemical Solubilities. Inorganic. By Arthur Messinger Comey, Ph.D. Pp. xx + 515. (London: Macmillan and Co., Ltd., 1896.)

THIS is a book about which it is impossible to get up any feeling of enthusiasm; but one cannot resist a sense of wonder and admiration at the patient, plodding spirit in which the compiler must have set about his weary task, and carried it on through months or years of labour to the dreary end. Of course he is an American. In no other nation of the earth using or abusing the English tongue would a man have been found to undertake such an enterprise; but why the busy, rushing life of that great country across the Atlantic should breed so many compilers of catalogues and bibliographies and indexes, especially of physical science, of books which Charles Lamb would have called no books, *biblia a-biblia*, it seems hard to say. The world ought to feel grateful to them, but usually it does not. It often uses such cyclopædias, though ready enough to grumble if it finds them less than perfect. In this volume the only smack of literary flavour is to be found in the preface, wherein the extract from "Peter Shaw's Chemical Lectures, publickly read at London in 1731 and 1732," shows that the plan of such a book was foreshadowed long before its accomplishment. For, according to the author, the first work that undertook to carry out the idea in its entirety was produced by Prof. F. H. Storer in 1864. All chemists are familiar with Storer's "First Outlines of a Dictionary of Solubilities of Chemical Substances," though long since out of print. It will at once be noticed that there is an important difference in the titles of the two works. Dr. Comey is, however, justified in using the expression "chemical solubilities," inasmuch as he does not confine his work to data concerning solutions in water and alcohol or other neutral solvents, but includes the action, for example, of acids upon metals, and the effects of various liquids, such as solutions of potash and aqueous acids. Moreover, certain physical facts are mentioned, such as changes of temperature on dilution, also any data obtainable regarding the boiling-points of solutions, and tables giving the specific gravities of aqueous solutions.

After all, the more modest title—"First Outlines"—adopted by Storer, seems to assume quite enough; for the materials for such a work amount at present to little more than a most miscellaneous collection of more or less inaccurate estimations of solubilities, without any clue as to the cause of solubility, and theories as to the condition of the dissolved substance still in conflict. This, however, has not deterred the compiler, who, on the whole, has done his work carefully and well. It would, perhaps, help the users—we can hardly speak of readers—of the Dictionary if in a future edition the general statements were somewhat amplified, and gathered together into an introductory chapter apart from the alphabetical array of details concerning particular cases. For example, it is obvious in regard to salts that the solubility in water is determined more by the nature of the negative radicle than of the metal. We can say truly that all nitrates are soluble in water except a few basic compounds, but we cannot predicate anything general concerning the solubility of the compounds, say, of lead. Some of these broad statements are given in the Dictionary, but they might be extended with advantage. A classification of the metals according to the action of water and of acids upon them might be given; it might also be worth while to state what is known of the colours of dissolved inorganic substances, concerning which there are some very curious facts which probably have an important significance could we only find the clue to their explanation.

From what has been said, it is obvious that this volume contains a mass of information brought together from a great variety of sources. It will certainly be found useful not only in the chemical laboratory, but also by the manufacturer and practical man to whom time is money. It may therefore be fairly described as one of those books which no chemist's library should be without.

OUR BOOK SHELF.

A Concise Handbook of British Birds. By H. Kirke Swann. Pp. 210. (London: John Wheldon and Co., 1896.)

THIS is a handy and serviceable reference book on British birds. It includes descriptions of the characteristics, distribution, and habits of every species on the British list, and the information, though brief, is generally sufficient for identification. The classification and nomenclature followed is practically that of the British Ornithologists' Union. The specific names of first describers are, however, adopted, and sub-species or races are distinguished by sub-numbers and trinominals. Ornithologists, and bird-lovers generally, will find Mr. Swann's book of practical value in the field, and very useful for ready reference in the study.

Practical Radiography. By H. Snowden Ward; with Chapters by E. A. Robins and A. E. Livermore. Pp. 80. (The Photogram, Ltd., 1896.)

THERE may be persons who furnish themselves with an outfit for Röntgen photography without having a knowledge of either electricity or photography. For such individuals, possessing aspirations without education in physical principles, this book has been written. The history of kathode rays and Röntgen's discovery occupies seven pages of the book. There is a chapter on the manufacture of an accumulator, and another describing how to make an induction coil. The remaining five chapters are taken up with descriptions of the apparatus and methods of Röntgen photography.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Are Specific Characters useful?

WITH the above title Mr. Alfred Russel Wallace brought before the Linnean Society on June 18 an important communication, which derived additional interest from the fact that he himself was present in full health and vigour, as well as from the presence of a large number of naturalists who have given attention to the questions arising from the consideration of the theory of the origin of species by natural selection.

In the course of the remarks which were offered by his audience at the conclusion of Mr. Wallace's paper, I ventured to point out that the consideration of the class of phenomena which Mr. Darwin had described under the title "correlation of variation," seemed to me to lead necessarily to the conclusion that very often characters which are obvious and distinctive marks of species may be not useful but useless, since such obvious species marks may be only superficial and non-significant phenomena "correlated" (as Mr. Darwin used that term) with other less obvious but really important life-saving peculiarities, which might quite well escape the observation of the describer of "specific characters." As instances of the phenomenon of "correlation," I referred to those cited by Mr. Darwin, such as the concomitance of a development of feathers on the feet with the webbing of the toes in certain breeds of pigeons, the concomitance of abnormal dentition with hairlessness of the body-surface in Chinese dogs, the concomitance of deafness with blue eyes in male white cats. A case which seemed to me most striking and suggestive in connection with the utility of specific characters was cited by me. It was that which had led Wells to propound a doctrine of "natural selection" many years before Darwin and Wallace had placed their views in 1858 before the Linnean Society—a case which Mr. Darwin cited in later editions of the "Origin of Species," and is familiar enough. Wells pointed out in a memoir communicated to the Royal Society in 1813, that persons with dark pigment in the skin are relatively immune to tropical fevers, as compared with fair-complexioned individuals. He argued that owing to this property of dark-skinned varieties of men, there would be a survival selection in tropical regions of such varieties, and that probably, or at any rate possibly, in this manner the black colour of tropical races might be accounted for. I mention this more or less hypothetical case as showing that an obvious and striking character, namely, that of black pigment in the skin, might become predominant, and conceivably might become a "specific character," although the blackness was not in itself a "useful," that is, a "life-preserving or progeny-ensuring" character, but merely the *accompaniment* of a power of resisting malarial germs, which we now have reason to believe consists in a special chemical activity of the leucocytes (phagocytes) of the blood and other tissues. From the consideration of this and other similar cases, I argued that many "specific characters" (that is to say, as defined by Mr. Wallace, characters which individually or in definite association with other characters constantly occur in one species and not in the other species of a genus) must be devoid of utility themselves, and appear merely as the "correlatives" or "concomitants" of really effective life-preserving or progeny-ensuring characters. I insisted, finally, on the very great importance of the correlation of parts in animal organisms, and the necessity of regarding animals (and presumably also plants) as most highly-wrought mechanisms in which no part can vary without the accompaniment of variation in some remote and (in our present state of knowledge) unexpectedly correlated part, and to a degree often excessive and (in our present state of knowledge) unaccountable. Thus, as Mr. Darwin himself pointed out, the selection of a given favourable variation may lead to excessive variation in a remote region of the organism, which in its turn will very often (but not necessarily always or at once) become the subject of further selection. Mr. Darwin appears to have deprecated, in conversation with Mr. Thiselton-Dyer (according to the latter's interesting statement in the debate on Mr. Wallace's paper), the invocation of this theory of "correlation" as an explanation of cases of apparently useless parts in animals or plants when under investigation, holding that our ignorance of the modes in which parts may be serviceable to an organism is so great that we should rather experiment and observe as to their possible utility than advance a theory which dismisses further inquiry. Whilst agreeing with Mr. Thiselton-Dyer as to the "immorality" (as he termed it) of a naturalist who favours theories which paralyse his activity as an observer and experimentalist (on which subject see the last paragraph of this letter), I yet think that, as seekers after true knowledge, we are bound to face the complex problem in all its aspects. The obvious character, as well as many less obvious characters, which we note as distinguishing one species from another, are not improbably, it must be admitted, in many cases concomitant phenomena of some other phenomenon which alone among them is effective in determining the preservation of the life, or the production of progeny in the case of the individuals so characterised.

At the same time I think that it may well be maintained that such secondary or concomitant characters are not long allowed to remain non-significant, and that sooner or later they fall under the moulding action of natural selection, becoming as they increase in volume either useful or injurious.

My chief object in writing this letter is to draw attention to the views of Prof. Weldon, who has for some time, as all zoologists know, been occupied in tabulating a very large series of measurements of growing crabs. When I had stated my views as to the importance of "correlation of variation," with which Mr. Meldola and Mr. Wallace subsequently expressed their complete agreement, Prof. Weldon declared, with some expressions of reluctance and regret—due, as he was good enough to say, from an old pupil to the teacher whom he is about to denounce and demolish—that to attempt to say which of two or more correlated growths is the cause of survival is unreasonable, and that when I suggested, even as a matter for consideration, that a certain germ-slaying quality in phagocytes accompanying a pigmented skin, rather than the pigment itself in the skin, is the cause of the survival of dark-skinned people in malarial regions, I was "absolutely illogical." "It is," said Prof. Weldon, "impossible logically to separate these two correlated phenomena. The coloured skin is as much a cause of the survival of the dark man as is the germ-destroying property of his blood."

I was at the time entirely unable to appreciate the drift of Prof. Weldon's thought. I was not prepared for an empty

wrangle in regard to the proper uses or improper uses of the word "cause." But I did remember that Mill says that the most vulgar form of "the fallacy of generalisation" is that which is expressed by the phrase "*post hoc* or *cum hoc, ergo propter hoc.*" I could not imagine how or why my friend Prof. Weldon had been led to make himself the defiant, not to say jubilant, champion of this fallacy. I have, on reading Prof. Weldon's paper in the *Proceedings* of the Royal Society, vol. lvii. 1894–95, found matter which throws light on the problem. It would appear that Prof. Weldon, in discussing his measurements of crabs, had already publicly adopted the logical position which so much astonished those who heard him at the Linnean Society. It appears that the fallacious process, which consists in ignoring the possibility of two concomitant phenomena being two independent consequences of one set of antecedents, gives an apparent value to the laborious measurement of crabs which, it seems, they would not possess if treated in a rational way. Prof. Weldon says (*loc. cit.*, p. 380): "It is the object of the present remarks to discuss the *effect* of small variations, as it may be deduced from the study of two organs in a single species. The case chosen is the variation, during growth and in adult life, of the dimensions of female *Carcinus mænas.*"

Further on he speaks of "the *effect* of small variations upon the chance of survival," and in close proximity occurs this passage: "The law of growth having been ascertained, the rate of destruction may be measured, and in this way an estimate of the *advantage* or *disadvantage* of a variation may be obtained." And again: "Knowing that a given deviation from the mean character is associated with a greater or less percentage death-rate in the animals possessing it, the *importance* of such a deviation can be estimated without the necessity of inquiring how that increase or decrease in the death-rate is brought about so that all ideas of functional adaptation become unnecessary." The title of the paper drawn up by a Committee, of which Prof. Weldon is a member, and in reference to which his own paper is written, stands: "An attempt to measure the death-rate due to the *selective* destruction of Carcinus mænas *with respect to* a particular dimension."

(The italics in these citations are mine.)

It appears to me that the language which I have italicised indicates that Prof. Weldon—in his interpretation of the fact ascertained by him, viz. that crabs with a particular proportion of frontal breadth are commoner in the adult condition than in younger stages—has deliberately departed from the simple statement which his observations warranted, viz. that such-and-such a proportion of frontal measurement accompanies survival, and has unwarrantably (that is to say unreasonably) proceeded to speak of the "effect" of this frontal proportion, to declare it to be a *cause* of survival, to estimate the "advantage" and "disadvantage" of this same proportion, and finally to maintain that its "*importance*" may be estimated without troubling ourselves to inquire how it operates, *or whether indeed it is operative at all.*

Such methods of attempting to penetrate the obscurity which veils the interactions of the immensely complex bundle of phenomena which we call a crab and its environment, appear to me not merely inadequate, but in so far as they involve perversion of the meaning of accepted terms and a deliberate rejection of the method of inquiry by hypothesis and verification, injurious to the progress of knowledge. E. RAY LANKESTER.

Oxford, June 30.

Are Specific Characters the Result of "Natural Selection"?

THE last meeting—on June 18—of the Linnean Society was one of very exceptional interest, because the survivor of the two illustrious naturalists who, on the same night—more than thirty-seven years ago—first enunciated in that Society's rooms the doctrine of the origin of species by "natural selection," read a highly interesting paper on that very subject.

The title of the paper, by Dr. Alfred R. Wallace, F.R.S., however, was "The Problem of Utility: Are specific characters always or generally useful?" But the author, in treating the question, expressly took for granted (as might surely have been expected of him) the doctrine common to him and the late Mr. Darwin. So the question was implicitly answered at once; for if species arise by "natural selection," then those characters which constitute them species must be due to the same cause, *i.e.* to utility. Thus the question really raised by Dr. Wallace was the old one, "Do species arise through 'natural selection'?"

This old question having been thus again started by its oldest advocate, a few words in reply to it may be permitted to one of its oldest opponents. Not that I was always an opponent. The doctrine of Messrs. Darwin and Wallace, as advocated by the late Prof. Huxley, was held by me from 1860 onwards for several years. There was no antecedent reason why it should be unwelcome to me, and, in fact, it was not at all so. It was whilst working at Lemuroids that doubts first suggested themselves, which afterwards became, for me, certainties.

It is one of those animals—the Potto—which has a specific character, the least likely of any that I know of to have been produced by "natural" or "sexual" selection—one which I cannot believe was ever occasioned by "utility," though it may have been so by another now suggested cause. It appears to me to be an indisputable fact that in certain groups of animals there are, somehow, present, innate tendencies to development along certain lines; different degrees of the realisation of which tendencies are characteristic of different species; and this without affecting the preservation of life. Thus amongst the Lemuroids there appears to be a tendency to diminish the size of the index finger, and this tendency culminates in the Potto.

In a section of the *Marsupialia* there seems to be a similar tendency to diminish the size of two digits of the foot, though I cannot believe that life has been saved at either the initial or the extreme stages of this progressive degradation.

Our own species supplies another example similar in character. The penial bone of the lower apes is a considerable structure, but in the Anthropoids it becomes so rudimentary, that the chimpanzee was believed to have none till the late Mr. Crisp exhibited the rudimentary representative of that structure at a meeting of the Zoological Society, as I well remember. In man it has, at least normally, entirely disappeared, and yet it is impossible to suppose that its progressive disappearance has been progressively useful as regards any form of "natural selection."

The existence of a latent tendency in a group of animals seems to us peculiarly well marked in the Birds of Paradise. The exceptional abnormalities of their plumage are so different in different species, that these could never have sprang from a common origin, but must have independently arisen in different modes in different species.[1]

Dr. Wallace said: "Accessory plumes and other ornaments originate at points of great nervous and muscular excitation." But the points of origin of abnormalities of plumage in these birds are so numerous and diverse, that such local excitations seem a very inadequate cause to account for them. Yet even if they were adequate, what would account for such varied localities of excitation in this particular group of birds alone?

But Dr. Wallace affirmed that such characters were utilised "for purposes of recognition," . . . "each ornament being really a 'recognition mark,' and therefore essential to both the first production and subsequent well-being of every species."

Let us suppose that a certain group of birds (A) have begun to vary in such a way that the males have acquired incipient secondary sexual markings or growths in their plumage, and that another group of birds (B) have begun to vary so that new tints, or plumage growths, appear equally in both sexes. The change must be small at first, and, indeed, Dr. Wallace said "the transition" is an "almost imperceptible process." But what influence can, at the same time, induce the males of the group (A) to seek for females newly modified but different from themselves, and the males of the group (B) to seek for females newly modified but like themselves? Why should the slightly modified new varieties object to mate with members of the hardly different parent stock? Yet if they did not so object in a majority of cases the new variety would soon disappear. Dr. Wallace told us that such marks must have been specially needed during the earlier stages of differentiation, yet at such early stages the much-needed "recognition marks" must have been at their minimum. This innate spontaneous impulse to breed together, thus supposed to arise in members of every incipient new variety whence every new species has arisen, is surely a very mysterious impulse. No doubt Dr. Wallace has evidence that it does in fact exist; but if so, we must admit that somehow a quasi voluntary process—a psychical character—has been pre-caused (if we must not say pre-ordained), which is a *sine qua*

[1] I called attention to this fact in my "Genesis of Species" in 1870. Since then the discovery of new species with new abnormalities has intensified the force of the argument.

non for the origin of new species, but the origin of which character is as mysterious as the origin of a species itself!

Dr. Wallace affirmed that "no other agency" than "natural selection" has been shown as a probable cause of specific characters—and therefore of species. Possibly not. But if an asserted cause (X) has been shown to be incapable of producing a certain effect, it is no use to say: "It must be (X) because you cannot bring forward any definite (not X) as efficient to produce that effect." Surely it is enough to reply: "The cause you assert is insufficient, and we must therefore still remain in an attitude of doubt and expectancy."

Dr. Wallace, however, in his recent paper did admit that the distinctive characters of some exceptional species might not have been due to "utility" or "natural selection"; but such an admission seems to me a fatal one, for if an unknown cause may have given origin to some species, why may not such cause have been the really efficient agent in the production of all species?

But Dr. Wallace years ago made (and he has never since repudiated his act) a truly important exception to the action of "natural selection."

A survey of the organic world cannot certainly be a scientific one if the highest of animals (man) be left out of the account, nor can man be said to be scientifically treated if his highest characteristics be altogether neglected.

Dr. Wallace cannot be accused of such neglect, and therefore with a survey of the organic world thus scientifically defective. Taking account of man's highest intellectual powers, he has declared that "natural selection" must have been incompetent to produce them, and agreed with me in the conviction that they require some further and higher explanation.

A recent number of NATURE has contained a review of Prof. Weismann's paper read at Leyden. Therein, that ardent Darwinian appears to have made several notable concessions which bear upon the question treated by Dr. Wallace. One of these is that "mimicry" cannot be accounted for by accidental, individual variation; he appears to say the same concerning certain co-adjustments of instinct and structure, and he fully concedes the truth asserted by Mr. Herbert Spencer and by myself—the truth, namely, that *panmixia* cannot explain the annihilation of rudimentary organs.

He, however, reaffirms his dictum that the idea of "teleological contrivances is inadmissible in science." But why? Who can deny to reason its right to investigate truth on all sides, and affirm that which appears to be evidently true with respect to any, including vital, processes? I adhere to the pronouncement of the world-renowned John Müller: "Physiology is no true science if not in intimate union with philosophy." Once more I must urge that man and his highest intellectual powers cannot be excluded from a scheme of nature which is truly scientific. Man has intelligence, and acts more or less frequently with intelligent purpose—"teleological contrivance"—and he exists in a universe which, as a whole, can never have been submitted to the action of "natural selection." The universe, therefore, even if eternal, cannot have unreason for its cause, or any power devoid of intelligence and purpose.

I believe the indisposition to accept such truths as a part of science is largely due to our common tendency to permit the intellect to be fettered by the imagination, thus giving rise to anthropomorphic mental images, the absurdity of which is assumed also to belong to those intellectual conceptions with which they have infinitely less to do than have the signs of the zodiac with the coherence of the solar system.

Saltburn-by-the-Sea, June 29. ST. GEORGE MIVART.

"The Reminiscences of a Yorkshire Naturalist."

WHEN reading this very interesting record of my old friend and colleague (of which you gave such an excellent review in your issue of June 25), I found that, in his recollections of the days when we were both professors at the Owens College, Manchester, Dr. Williamson has been mistaken as to the details of Principal Scott's retirement. Mr. J. Holme Nicholson (late Registrar of this College) confirms my memory as to dates, and, at Mrs. Williamson's request, I ask you to kindly insert, in your forthcoming number, the following correction in her late husband's graphic account of the early struggles through which Owens College had to pass on the way to its present high position as an institution for sound instruction in natural science and original research.

At page 140 of the "Reminiscences," there occurs the following passage: "Dr. Scott's resignation (May 28, 1857) robbed Manchester of a man of rare culture, and his death a few months later is said to have taken from the world more Dantesque learning than was left behind." There are two errors in this passage: in the first place, Dr. Scott did not sever his connection with Owens College in 1857; he resigned his principalship, but not his chairs of Logic, Moral and Mental Philosophy, and of Comparative Grammar and English Language and Literature, which he continued to hold until his death. Secondly, he died on January 12, 1866, and therefore not *a few months*, but *nearly nine years* after his resignation of the principalship. Consequently, it is a mistake to infer that Manchester was robbed of his presence and the advantages of his learning in 1857.

This correction is the more important because Dr. Williamson's words, above quoted, and their context, seem to convey, I am sure quite unintentionally, the impression that Dr. Scott's death was hastened by his resignation of the principalship; whilst, on the contrary, his relief from one of his many arduous duties probably prolonged his interesting and valuable life.

E. FRANKLAND.

The Tsetse Fly.

IN the excellent review of the Tsetse fly-disease, which appeared in NATURE of April 16, Mr. Walter F. H. Blandford accepts with some reserve the observation made by Dr. David Bruce, that the fly is *viviparous* "as the fly has not yet been bred from the puparium."

I pointed out to Dr. Bruce, while he was investigating the disease, that, with the systematic arrangement of Diptera now followed, I could hardly conceive the *Glossina* being viviparous; and I suggested the possibility of another fly being taken for the Tsetse. Dr. Bruce has not only been most emphatic in his reassertion, but I have myself since bred from three puparia, sent by him for that purpose, what is most certainly *Glossina morsitans*, Westwood. L. PÉRINGUEY.

South African Museum, Cape Town, June 15.

MY hesitation in accepting unreservedly Dr. Bruce's account of the reproduction of *Glossina* was due to a suspicion, not that he had mistaken some other fly for it, but that the extruded larvæ might turn out to be those of a parasitic form, probably Tachinid. Mr. Péringuey's letter is most welcome as supplying the final proof of an extremely important fact, both economically and zoologically, in the insect's life-history.

There is much variety in the larval life of *Muscidæ*; and in *Stomoxys*, the genus most nearly allied to *Glossina*, the larvæ are normally scatophagous, but that of *S. calcitrans* has been occasionally found mining the leaves of burdock, coltsfoot and deadly nightshade.

Unfortunately, till proof is complete that Nagana is contracted under natural conditions from Tsetse-infection only, which is as yet far from being the case, we cannot console ourselves with the idea that the progressive extinction of African wild game must soon render the disease a thing of the past.

July 6. WALTER F. H. BLANDFORD.

The Salaries of Science Demonstrators.

I SHOULD be glad if you would allow me the opportunity of endorsing Dr. Baker's protest contained in his letter in your issue of July 2, against the totally inadequate salaries offered by University Colleges to demonstrators and assistant lecturers in science.

Taking the subject of chemistry only: on looking over the official returns for the year 1893-4, made by eight of the University Colleges participating in the Treasury grant of £15,000, it will be seen that whereas the average salary paid to the professor is over £700, that of the assistant lecturers and demonstrators is under £150, and in several cases below £100 per annum.

No one acquainted with what is required of them will maintain that the professors are overpaid, but all must admit that the remuneration of the lecturers and demonstrators is absurdly out of proportion.

Compare for a moment the work done by the two classes of teachers. The occupant of a chair of Chemistry in a University

College is too often bound down by the exigencies of examinations to the delivery of certain set lecture courses, and these, together with his own researches and the performance of the many administrative duties that fall to his lot, occupy almost the whole of his time. Let him possess the master-mind of a Hofmann, his hurried visits to his laboratory afford comparatively slight opportunity for the exercise of its full effect on the student. The demonstrator, on the contrary, bears the brunt of the difficult and harassing tutorial work in his close contact with the student in the laboratory, and upon the demonstrator's ability and manner of teaching will depend, in great measure, the student's future style of work. For this a grateful University College gives him rather less than it pays to its janitor, and much less than half the amount received by its travelling dairy-maid !

I am afraid that the cause of this very real injustice will be found, in part, in the influence of our older universities, where until recently lectures were everything and practical work was naught. Members of these universities on college councils still seem to cling to the old idea, and the majority of the remaining members, probably excellent men of business or affairs, have somewhat hazy notions of scientific educational work ; the Professors, who alone of the teaching staff obtain representation on the governing body, are, after all, but human, and can scarcely be expected to labour to disabuse them.

I fear that, as a body, demonstrators and lecturers are scarcely influential enough to approach the Chancellor of the Exchequer with a view to his imposing such conditions that the renewal of the Treasury grant shall be made to depend upon the redress of their wrongs ; still the injustice of their treatment is undeniable, and perhaps some of your readers can suggest a remedy.

SAVILLE SHAW.

A Solar Halo.

SHORTLY after 7 o'clock in the evening of July 2, a solar halo was observed from Putney Bridge, West London.

The appearance consisted of portions of the inner halo (22° from the sun) situated just at the same height above the horizon as the sun. The halo was of a distinct red on the inside of the circle, followed by yellow and by a faintly bluish white light on the outside. There was also a faint parhelion on the right side, just outside of the halo.

Above the sun, at a point where the vertical through the sun would have cut the circular halo, there was, instead of the latter, an inverted arch of somewhat hyperbolic shape, the arms of the hyperbola extending upwards and enclosing an angle greater than a right angle. The faint prismatic colours of this arch were placed so that the red was nearest to the sun, and the apex of the inverted arch must have been 22° distant from the sun. The height of the sun above the horizon was estimated to be about 14°, and the phenomenon lasted ten minutes after it had been first observed. The sky was somewhat cloudy.

West Kensington. H. WARTH.

An Optical Illusion.

WHILE doing some photographic work with a light from a Welsbach burner, which shone through a small ground glass window in a dark-room, I noticed that when a lamp emitting red rays from its vertical sides was placed in a position so that its top was illuminated by the white light from the window, and while in this light it was then moved by hand to and fro in a horizontal plane, the top appeared to be loose, or displaced in opposite directions to the red sides. The top was of bright tin and its surface sufficiently irregular to cast slight shadows, which rendered the effect very marked.

This illusion is no doubt due to a physiological action at the retina, in which the impression produced by the white or grey light persists longer than that from the red, causing an apparent lag of the top. The persistency may be still further accounted for when the fact is borne in mind that the lag could only be obtained with weak lights in a dark-room, and therefore with the pupil of the eye largely expanded, and in consequence a relative increase of intensity of the white over the red light upon retinal areas of different sensibility.

Lamplight or daylight can be used instead of a Welsbach. I found it convenient to vary the intensity and colour of the lights by superposing sheets of coloured tissue-papers.

New Rochelle, N.Y. F. H. LORING.

Food of Chameleons.

I do not know whether you care to insert a modest natural history communication, for I apprehend but few of your readers are country naturalists. If you do, it is to this effect.

It is not easy to keep chameleons alive long in this country, owing to the difficulty of procuring their proper diet.

I am keeping a Madagascar one, and he thrives very well. The food he seems to prefer to all other is the common green fly with a metallic lustre ; these he takes at once in preference to the finest bluebottles, and when he protrudes his curious long tongue, armed with some glutinous matter, the direction is unerring, and woe to the fly. The chameleonic colour changes are most interesting. E. L. J. RIDSDALE.

Rottingdean.

Röntgen Rays.

MANY tubes for Röntgen ray researches have the edge of the kathode mirror opposite the short neck, and in such cases the expedient described by Mr. Porter in your issue of the 18th ultimo, can very easily be carried out by fitting an india-rubber ring on this neck, winding two coils of copper wire round it, and leaving two or three inches free at one end, which is then bent so as to bring the point sufficiently near to the kathode loop.

An application of the Röntgen rays has been made in the small local museum here, which promises to make it more generally attractive and useful. Skiagrams of suitable specimens have been taken, and prints from these placed alongside the specimens, so that their external form and the bony structure which supports it may be compared at a glance.

Keith, N.B., July 3. ALEX. THURBURN.

A Curious Connection.

IF new, perhaps the following fact, observed by me, may be worth publishing. In my kitchen I have a mantle on the gas-burner. At present the mantle is in a dilapidated state, and the light defective. I find, however, that, when the water-tap over the kitchen sink is running, the light greatly increases in brilliancy, maintaining that brilliancy as long as the water is running. MARGARET MCEVOY.

THE INTERNATIONAL CATALOGUE CONFERENCE.

THE International Conference organised by the Royal Society to consider the preparation and publication of an International Catalogue of Scientific Literature was opened in the apartments of the Society at Burlington House on Tuesday. Upon the importance of such a catalogue it is unnecessary to comment here. The Royal Society has steadily attacked the problem of recording and indexing scientific literature, since the middle of this century, when the great author-index was commenced. More than thirty years ago the Council of the Society resolved that the catalogue according to authors should be followed by an index according to subjects, and a start was made in 1893. But, as Lord Kelvin pointed out in his last anniversary address, "the continuation of such a work was almost beyond the resources of the Royal Society, and therefore about two years ago a Committee was appointed to take into consideration a suggestion that the preparation of complete indexes should be effected by international co-operation." The conference now being held is the outcome of this conclusion. Only by securing international co-operation could such a work as that contemplated by the Royal Society be satisfactorily carried out. It is therefore a matter of extreme congratulation that the proposal has been so warmly supported by Governments and Scientific Societies in all parts of the world, as shown by the distinguished men who have been delegated to take part in the conference. The enterprise is one in which all men of science are interested, but of the magnitude of which it is only possible to have a faint conception. To develop a comprehensive and practicable scheme will be a difficult task, but with a conference constituted like that now

sitting the work will be well considered, and we may confidently expect as a result the outlines of a system which will have international confidence and support.

From the following list of delegates to the Conference it will be seen that nearly all the Governments of civilised countries are represented, and most of the leading scientific societies of the world.

The delegates in attendance are:—AUSTRIA—Prof. Ernest Mach (Member of the Kaiserliche Akademie der Wissenschaften, Vienna); Prof. Edmund Weiss (Member of the Kaiserliche Akademie der Wissenschaften, Vienna). BELGIUM—M. H. La Fontaine (Membre, Institut International de Bibliographie, Brussels); M. Paul Otlet (Membre de l'Institut International de Bibliographie); M. de Wulf (Membre de l'Institut International de Bibliographie). DENMARK — Prof. Christiansen (Universitet, Copenhagen). FRANCE—Prof. G. Darboux (Membre de l'Institut de France); Dr. J. Deniker (Librarian, Muséum d'Histoire Naturelle, Paris). GERMANY—Prof. Schwalbe (Berlin); Prof. Dziatzko (Göttingen); Prof. Walther Dyck (Mitglied der K. Bay. Akad. der Wiss. zu München); Prof. Van't Hoff (Mitglied der K. P. Akademie der Wissenschaften zu Berlin); Prof. Möbius (Mitglied der K. P. Akademie der Wissenschaften zu Berlin). GREECE—M. Avierinos M. Averoff (Greek Consul at Edinburgh). HUNGARY—Prof. August Heller (Librarian, Ungarische Akademie, Buda-Pesth); Dr. Theodore Duka (Membre, Academie Hongroise des Sciences, Buda-Pesth). ITALY—General Annibale Ferrero (Italian Ambassador in London). JAPAN—Assistant Professor Hantaro Nagaoka (University, Tokio); Assistant Professor Gakutaro Osawa (Medical College, Tokio). MEXICO—Señor Don Francisco del Paso y Troncoso. NETHERLANDS—Prof. D. J. Korteweg (Universiteit, Amsterdam). NORWAY—Dr. Jörgen Brunchorst (Secretary, Bergen Museum). SWEDEN—Dr. E. W. Dahlgren (Librarian, Kongl. Svenska Vetenskaps Akademie, Stockholm). SWITZERLAND—M. C. D. Bourcart (Swiss Minister in London); Prof. Dr. F. A. Forel (Président du Comité Central de la Société Helvétique des Sciences Naturelles). UNITED KINGDOM — Representing the Government: Right Hon. Sir John E. Gorst, Q.C., M.P. (Vice President of the Committee of Council on Education). Representing the Royal Society of London: Prof. Michael Foster (Sec. R.S.); Prof. H. E. Armstrong, F.R.S.; Prof. Liversidge, F.R.S; Mr. J. Norman Lockyer, C.B., F.R.S.; Dr. Ludwig Mond, F.R.S.; Prof. A. W. Rücker, F.R.S. UNITED STATES—Dr. John S. Billings (U.S. Army); Prof. Simon Newcomb, For. Mem. R.S. (U.S. Nautical Almanac Office). CANADA—The Hon. Sir Donald A. Smith, G.C.M.G. (High Commissioner for Canada); CAPE COLONY—Mr. Roland Trimen, F.R.S.; Dr. David Gill, F.R.S. INDIA—Lieut.-General Richard Strachey, R.E., F.R.S. NATAL—Walter Peace, Esq., C.M.G. (the Agent-General for Natal). NEW SOUTH WALES—(Awaits confirmation). NEW ZEALAND—The Hon. W. P. Reeves (Agent-General for New Zealand). QUEENSLAND—The Acting Agent-General for Queensland.

Subjoined is the official report of the preliminary proceedings on Tuesday.

Prof. Foster (Sec. R.S.) moved that Sir J. Gorst act as provisional President for the purpose of organising the Conference.

The resolution, having been unanimously accepted, Sir John Gorst welcomed the delegates.

Prof. Armstrong gave a brief account of the work done by the Royal Society in arranging for the conference, as well as of the work to be accomplished.

The following resolutions were then agreed to.

(*a*) That each delegate shall have a vote in deciding all questions brought before the Conference.

Que chaque délégué aura un vote pour décider toutes les questions soumises à la Conférence.

Dass jeder Delegirte eine Stimme haben soll bei Entscheidung aller Fragen die vor die Conferenz gebracht werden.

(*b*) That English, French and German be the official languages of the Conference, but that it shall be open for any delegate to address the Conference in any other language, provided that he supplies for the *procès verbal* of the Conference a written translation of his remarks into one or other of the official languages.

Que l'Anglais, le Français, et l'Allemand seront les langues officielles de la Conférence, mais que chaque délégué pourra s'adresser à la Conférence dans n'importe quelle autre langue, pourvu qu'il remettra pour le procès verbal de la Conférence une traduction écrite de ses observations dans l'une des langues officielles.

Dass Englisch, Französisch und Deutsch die offiziellen Sprachen der Conferenz sein sollen, dass es aber jedem Delegirten freistehen soll, bei die Conferenz in einer andern Sprache zu sprechen, vorausgesetzt, dass er für das Protocoll der Conferenz eine schriftliche Uebersetzung seiner Rede in einer der offiziellen Sprachen liefert.

General Ferrero moved that Sir John E. Gorst be the President of the Conference. The motion having been unanimously accepted,

Sir John Gorst nominated as Vice-Presidents: General Ferrero, Prof. Darboux, Prof. Mach, Prof. Möbius, and Prof. Newcomb.

It was further resolved—

(*c*) That Prof. Armstrong be the Secretary for the English language; that Prof. Forel be the Secretary for the French language; and that Prof. Dyck be the Secretary for the German language.

(*d*) That the Secretaries, with the help of shorthand reporters, be responsible for the *procès verbaux* of the proceedings of the Conference in their respective languages.

The President and Council of the Royal Society gave a reception to the delegates on Monday; and on Tuesday evening the delegates were entertained at a banquet at the Hôtel Métropole. The chair was taken by the President, Sir Joseph Lister, and there were also present Sir F. Abel, Agent General for British Columbia, Agent-General for Cape of Good Hope, Agent-General for Natal, Agent-General for New South Wales, Agent-General for New Zealand, Agent-General (acting) for Queensland, Agent-General for Western Australia, Prof. Armstrong, M. Averoff, Prof. Ayrton, Prof. Barker, Belgian Minister, Mr. Bidder, Dr. J. Billings, Sir F. Bramwell, Mr. H. Brown, Dr. Brunchorst, Dr. Brunton, Mr. Burbury, Dr. Champneys, Prof. Christiansen, Mr. Clough, Dr. Dahlgren, Prof. Darboux, Dr. Deniker, M. De Wulf, Dr. T. Duka, Prof. Dyck, Prof. Dziatzko, Dr. Elgar, Mr. C. E. Fagan, Dr. Fick, Mr. Fletcher, Sir W. H. Flower, Prof. Forel, Prof. Forsyth, Prof. M. Foster, Dr. Frankland, Sir D. Galton, Sir Robert Giffen, Dr. Gill, Dr. Gladstone, Sir John Gorst, Greek Chargé d'Affaires, Prof. Greenhill, Mr. Harrison, Prof. Heller, High Commissioner for Canada, Italian Ambassador, Japanese Minister, Prof. J. V. Jones, Mr. Keltie, Lord Kelvin, Mr. Kempe, Prof. Kennedy, Prof. Korteweg, M. La Fontaine, Prof. Lapworth, Prof. Liversidge, Mr. Lockyer, Mr. MacAlister, Mr. McClean, Prof. Mach, Mr. Mackey, Prof. McLeod, Major MacMahon, Mexican Minister, Dr. Mill, Prof. Möbius, Dr. Mond, Mr. R. L. Mond, Dr. Mott, Mr. Moulton, Prof. Nagaoka, Dr. Neale, Prof. S. Newcomb, Prof. Osawa, M. Otlet, Senor Don Paso y Troncoso, Prof. Perry, Portuguese Minister, Prof. Poulton, Mr. Preece, Pres. Soc. Chem. Industry, Lord Rayleigh, Prof. Roberts-Austen, Prof. Rücker, Mr. H. Saunders, Herr Schwalbe, Dr. Sclater, Prof. Sherrington, Prof. Sprengel, Sir Gabriel Stokes, Swedish and Norwegian Minister, Swiss Minister, Capt. Swithinbank, Rev. S. Thompson-Yates, Mr. Spencer

B. Todd, Treasurer Roy. Soc., Mr. R. Trimen, Prof. Unwin, Prof. Van't Hoff, Gen. Walker, Prof. Weiss, Mr. C. Welch, Dr. Wynne.

Sir Joseph Lister, in giving the toast of "Science in all Lands," remarked that it would be impertinent in such company to dwell on the advantages which science conferred upon humanity or upon the pleasures which she gave to those who had the privilege of cultivating her various branches. They were agreed that if the mighty project upon which the conference had met was brought to a successful issue it would very greatly promote the advance of science.

The toast was responded to by the Italian Ambassador (General Ferrero), who said that England had always taken a leading, sometimes the first, place in science from the days of Newton to those of Lord Kelvin, and the Royal Society had worthily represented the nation in its work for the advancement of science.

Prof. Mach also responded, remarking that men of science recognised no distinction of race or nationality, and they were all glad to co-operate with Englishmen in a work in which all men of science were interested, especially as the work was done under the auspices of the Royal Society.

Dr. Billings proposed "Success to the Conference and the Catalogue" in a humorous speech. He suspected that classification began in the Ark. Science was now getting so large and various that the projected summary would be of extreme value; but he did not quite know to what it would lead. If their object in carrying out this catalogue were achieved, they might anticipate a time when men and things and thoughts also would be catalogued. They might look forward down the vista of years to the time when a stranger in Hyde Park would see a passer-by with such a number as 26·053, and would then at once appreciate his status in every respect, and when the novelist would proudly show that his heroine had twenty-six points in her character, while a rival writer had only achieved nineteen.

Prof. Darboux, Prof. Möbius, and Prof. Forel briefly acknowledged the toast.

The Treasurer of the Royal Society (Sir John Evans) proposed "The Guests," and expressed the hope that the deliberations of the conference would be ultimately successful.

Sir Donald Smith, High Commissioner for Canada, responded.

The Belgian Minister proposed "The Royal Society," which he said, was the mother and model of all similar societies in Europe, and was based on the principle that science knew nothing of nationality. The president was a great master of antiseptic surgery; if he could only introduce the principles by which he was so distinguished into the realm of politics and international relations he would be one of the greatest benefactors of the human race.

The President, in response, said the society was proud to take the lead in so important a work as that of the Conference. It had given him personally much satisfaction to learn that the Conference on the first day had been exceedingly successful, and there was no doubt that if this movement was carried out, as they hoped it would be, it would prove of great help to science in all its branches.

ON THE MOTION OF A HETEROGENEOUS LIQUID, COMMENCING FROM REST WITH A GIVEN MOTION OF ITS BOUNDARY.[1]

I USE the word "liquid" for brevity to denote an incompressible fluid, viscid or inviscid, but inviscid unless the contrary is expressly stated. A finite portion of liquid, viscid or inviscid, being given at rest, within a bounding vessel of any shape, whether simply or multiply continuous; let any motion be *suddenly* produced in some part of the boundary, or throughout the boundary, subject only to the enforced condition of unchanging volume. Every particle of the liquid will instantaneously commence moving with the determinate velocity and in the determinate direction, such that the kinetic energy of the whole is less than that of any other motion which the liquid could have with the given motion of its boundary.[1] This proposition is true also for an incompressible elastic solid, manifestly; (and for the ideal "ether" of *Proc. R.S.E.*, March 7, 1890; and Art. xcix. vol. iii. of my Collected Mathematical and Physical Papers). The truth of the proposition for the case of a viscous liquid is very important in practical hydraulics. As an example of its application to inviscid and viscous fluid and to elastic solid consider an elastic jelly standing in an open rigid mould, and equal bulks of water and of an inviscid liquid in two vessels equal and similar to it. Give equal sudden motions to the three containing vessels: the instantaneous motions of the three contained substances will be the same. Take, as a particular case, a figure of revolution with its axis vertical for the containing vessel and let the given motion be rotation round this axis suddenly commenced and afterwards maintained with uniform angular velocity. The initial kinetic energy will be zero for each of the three substances. The inviscid liquid will remain for ever at rest; the water will acquire motion according to the Fourier law of diffusion of which we know something for this case by observation of the result of giving an approximately uniform angular motion round the vertical axis to a cup of tea initially at rest. The jelly will acquire laminar wave motion proceeding inwards from the boundary. But in the present communication we confine our attention to the case of inviscid liquid.

The now well-known solution[2] of the minimum problem thus presented, when the bounding surface is simply continuous, is, simply: that the initial motion of the liquid is irrotational. That the *initial* motion *must be irrotational*[3] is indeed obvious, when we consider that the impulsive pressure by which any portion of the liquid is set in motion is everywhere perpendicular to the interface between it and the contiguous matter around it, and therefore the initial moment of momentum round any diameter of every spherical portion, large or small, is zero. But that irrotationality of the motion of every spherical portion of the liquid suffices to determine the motion within a simply continuous boundary having any stated motion, is not obvious without mathematical investigation.

Whether the boundary is simply continuous, or multiply continuous, irrotationality suffices to determine the motion produced, as we now suppose it to be produced, from rest by a given motion of the boundary.

Now in a homogeneous liquid acted on by no bodily force, or only by such force (gravity, for example) as could not move it when its boundary is fixed, the motion started from rest by any movement of the boundary remains always irrotational, as we know from elementary hydrokinetics. Hence, if at any time the boundary is suddenly or gradually brought to rest, the motion of every particle of the liquid is brought to rest at the same instant. But it is not so with a heterogeneous liquid. Of the following conclusions Nos. (1), (2), (3) need no proof. To prove

[1] Read at the Royal Society of Edinburgh, by Lord Kelvin, on April 6.

[1] *Cambridge and Dublin Mathematical Journal*, February 1849. This is only a particular case of a general kinetic theorem for any material system whatever, communicated to the Royal Society, Edinburgh, April 6, 1863, without proof (*Proceedings*, 1862-63, p. 114), and proved in Thomson and Tait's "Natural Philosophy," sec. 317, with several examples. Mutual forces between the containing vessel and the liquid or elastic solid, such as are called into play by viscosity, elasticity, hesivity (or resistance to sliding between solid and solid), cannot modify the conclusion, and do not enter into the equations used in the demonstration.

[2] Thomson and Tait's "Natural Philosophy," sec. 312.

[3] That is to say, motion such that the moment of momentum of every spherical portion, large or small, is zero round every diameter.

No. 4 remark that as long as there is any motion of the heterogeneous liquid within the imperfectly elastic vessel the liquid must be losing energy; and the energy cannot become infinitely small with any finite spherical portion of the liquid homogeneous.

(1) The initial motion of a heterogeneous liquid is irrotational only at the first instant after being *quite suddenly* started from rest by motion of its boundary. Whatever motion be subsequently given to the boundary the motion of the liquid is never again irrotational. Hence

(2) If the boundary be suddenly brought to rest at any time, the liquid, unless homogeneous throughout, is not thereby brought to rest; and it would go on for ever with undiminished energy if the liquid were perfectly inviscid and the boundary absolutely fixed. The ultimate condition of the liquid, if there is no *positive* surface tension in the interfaces between heterogeneous portions, is an infinitely fine mixture of the heterogeneous parts.[1] And, if there were no gravity or other bodily force acting on the liquid, the density would ultimately become uniform throughout. Take, for example, a corked bottle half full of water or other liquid with air above it given at rest. Move the bottle and bring it to rest again: the liquid will remain shaking for some time. An ordinary non-scientific person will scarcely thank us for this result of our mathematical theory. But, when we tell him that if air and the liquid were both perfectly fluid (that is to say perfectly free from viscosity), the well-known shaking of the liquid surface would, after a little time, give rise to spherules tossed up from the main body of the liquid; and that the shaking of the liquid, left to itself in the bottle supposed perfectly rigid, will end in spindrift of spherules which would be infinitely fine if the capillary tension of the interface between liquid and air were infinitely small, he may be incredulous unless he tends to have faith in all assertions made in the name of science.

(3) If the boundary is an enclosing vessel of any real material (and therefore neither perfectly rigid nor perfectly elastic), and if it is laid on a table and left to itself, under the influence of gravity, the liquid, supposed perfectly inviscid, will lose energy continually by generation of heat in the containing vessel, and will come asymptotically to rest in the configuration of stable equilibrium with surfaces of equal density horizontal and increasing density downwards.

(4) With other conditions as in (3), but no gravity, the ultimate configuration of rest will be infinitely fine mixture (probably, I think of equal density throughout). Consider, for example, two homogeneous liquids of different densities filling the closed vessel, or a single homogeneous liquid not filling it. As an illustration, take a bottle half full of water, and shake it violently. Observe how you get the whole bottle full of a mixture of fine bubbles of air, nearly homogeneous throughout. Think what the result would be if there were no gravity, and if the water and air were inviscid and the bottle shaken as gently as you please; and if there were perfect vacuum in place of the air; or, if for air were substituted any liquid of density different from that of water.

See also *Philosophical Magazine*, 1887, second half-year: "On the formation of coreless vortices by the motion of a solid through an inviscid incompressible fluid"; "On the stability of steady and of periodic fluid motion"; "On maximum and minimum energy in vortex motion."

THE RETURN OF BROOKS'S COMET.

ON July 6, 1889, Mr. W. R. Brooks, of Geneva, New York, U.S.A., discovered a somewhat faint, telescopic comet at R.A. 356°, Dec. 9° south, in the southern region of Pisces. It had a short spreading tail, and was moving slowly to the E.N.E.

Observations in a few days enabled the orbit to be computed, and the small inclination (6°) intimated that the comet was probably one of short period. This proved to be the case after further observation, and the time of revolution was determined as about seven years. Otto Knopf, from three positions obtained at Mount Hamilton on July 8, at Dresden July 30, and at Vienna on August 19, deduced the period as 7·286 years. The comet was followed until January 1890, and from the whole series of observations Prof. S. C. Chandler found a period of 7·073 years, and that the orbit at aphelion approaches very closely to the orbit of the planet Jupiter. From March to July 1886, the distance of the comet and planet appears to have been less than 10,000,000 miles. The theory was suggested by Prof. Chandler that the comet may be identical with Messier-Lexell's comet of 1770; but Dr. C. L. Poor, on reinvestigating the matter, found little evidence in support of the idea.

The possible connection of the comet with that of 1770 is by no means the only interesting feature of this object. On August 1, 1889, Prof. E. E. Barnard observed that the comet was broken up into several detached fragments. It had previously been seen single, and had been submitted to pretty general observation without anything remarkable having been detected; but on the night of August 1, it appeared to have been suddenly shattered by some extraordinary forces or vicissitudes of a very mysterious character. One of the smaller fragments, together with the largest mass, remained visible for several months, moving in concentric paths, and forming a very interesting and rare telescopic spectacle.

The comet was a fairly conspicuous object in telescopes, but it was not visible to the unaided eye. Its apparent motion was very slow, for early in November its position was only seven degrees north of the place it had occupied four months before.

Dr. Poor fixed the next perihelion passage for November 4, 1896, and an ephemeris was prepared by Bauschinger for the spring and summer of 1896, as it was expected the comet might be picked up some months before its arrival at perihelion. This expectation has been fully realised, for the comet was re-discovered on the night of June 20 by M. Javelle, using the 30-inch refractor of the observatory at Nice. Its place was almost identical with that given in the ephemeris, and the re-discovery of the comet may therefore be regarded as another triumph for mathematical astronomy.

This comet should prove an extremely interesting object in regard to its physical appearance and changes of aspect. At the present time it is in Aquarius a little west of *Delta* in that constellation, and its position during the next few weeks will be nearly stationary. The ephemeris by Bauschinger is as follows:—

1896.	R.A. h. m. s.	Decl. ° ′ ″	Log. Δ	Brightness.
July 15 ...	22 39 1 ...	−18 9 53 ...	0·1124 ...	1·14
19 ...	39 58 ...	12 28 ...	0·0992 ...	1·22
23 ...	39 44 ...	16 28 ...	0·0866 ...	1·31
27 ...	39 24 ...	21 49 ...	0·0746 ...	1·40
31 ...	38 38 ...	27 52 ...	0·0633 ...	1·50
Aug. 4 ...	37 26 ...	34 44 ...	0·0529 ...	1·59
8 ...	35 50 ...	41 51 ...	0·0436 ...	1·68
12 ...	33 51 ...	48 48 ...	0·0353 ...	1·76
16 ...	22 31 34 ...	−18 55 2 ...	0·0284 ...	1·84

Thus the comet is likely to be visible throughout the present summer and ensuing autumn, for its brightness is gradually increasing, and it will remain in a favourable position all the time. Its southern declination of more than 18° is, however, rather unfortunate, as its altitude is only about 20°, so that observers will require to watch it from a position commanding a good open view of the southern sky.

W. F. DENNING.

NOTES.

DR. N. BUSCH, of Dorpat, has undertaken, at the request of the University of Dorpat and the Russian Geographical Society of St. Petersburg, a botanical investigation of the Caucasus. He proposes to visit the hitherto unexplored sources of the rivers Teberda and Maruch in Northern Caucasus.

THE Goldsmiths' Company has contributed a second donation of £1000 to the special funds of the research department of the Imperial Institute, to be applied to the extension of the laboratories and to their better equipment. The Salters' Company has established a Research Fellowship of the value of £150 per annum, in connection with the scientific department, tenable by chemists thoroughly qualified to undertake the investigation of new or little-known natural products received by the Institute from the colonies and India.

A ROYAL Commission has been appointed "to inquire and report what administrative procedures are available and would be desirable for controlling the danger to man through the use as food of the meat and milk of tuberculous animals, and what are the considerations which should govern the action of the responsible authorities in condemning for the purposes of food supplies animals, carcasses, or meat exhibiting any stage of tuberculosis." The Commissioners are Sir Herbert Maxwell, Dr. Richard Thorne Thorne, C.B. (medical officer of the Local Government Board), Mr. George Thomas Brown, C.B., Mr. Harcourt Everard Clare, Mr. Shirley Forster Murphy (member of the Royal College of Surgeons), Mr. John Speir, and Mr. Thomas Cooke Trench.

THE death is announced of Prof. E. Curtius, the distinguished Professor of Archæology in the Berlin University.

PROF. AUGUST KEKULÉ V. STRADONITZ, Professor of Chemistry in the University of Bonn, died on Monday, at the age of sixty-six.

THE Vienna Academy of Sciences announces as the subject of the Baron von Baumgartner prize of 1000 florins, "Extension of the Knowledge of the extreme Ultra-violet Rays." The prize will be awarded in 1899.

FROM a special number of their *Atti*, we learn that the Reale Accademia dei Lincei (of Rome) has made the following awards: Of two prizes given by the King of Italy, one for chemistry and the other for philosophical science, the first has been divided equally between Prof. Luigi Balbiano, of the University of Rome, for his monograph on certain compounds of the pyridine series, and Prof. Raffaele Nasini, of the University of Padua, for a series of twenty-seven papers on chemical physics. The prize for philosophy has not been awarded. Two prizes of 1500 lire, given by the Minister of Public Education, have been awarded—one for mathematics, the other for philology. For the mathematical prize eight candidates have submitted essays, and the prize has been adjudged to Prof. Geminiano Pirondini, of Parma, in consideration of eleven printed and written papers on geometry. The philological prize has been divided between Profs. Filippo Sensi, Silvio Pieri, G. B. Camozzi, Antonio Fiammazzo, and Oreste Antognoni. Of a further prize, given by Signor Enrico Santoro (an Italian residing in Constantinople), for mechanical inventions relating to weaving or spinning, the award has been postponed for a couple of years. These awards were announced at the twenty-first anniversary commemoration of the revival of the Academy on June 7, in presence of the King and Queen of Italy.

THE prize awards of the French Société d'Encouragement, for 1896, were announced at the recent annual general meeting. The Prix Giffard, for distinguished services to French industry, is of the value of 6000 francs; but this year, on account of exceptional merit, it has been increased to 10,000 francs and divided equally between D. Legat, for his mechanical works, and the family of the late A. Martin, renowned for his optical researches. The Grand Gold Medal, awarded each year to the author whose works have exercised the greatest influence on the progress of French industry in the preceding six years, was this year in the gift of the Comité des Arts mécaniques, who have voted it to F. G. Kreutzberger, the inventor of numerous improvements in machinery. M. Effront has been awarded the Prix Parmentier of 1000 francs for his works on alcoholic fermentations. The prize of 1000 francs for an oil motor has been gained by the Priestman motor. M. Lefèvre has obtained the prize of 2000 francs for a publication useful to chemical industry, by his remarkable "Traité des matières colorantes," reviewed in these columns on April 30 (vol. liii. p. 603). The Prix Melsens, for the author of an application of physics or chemistry to electricity, ballistics, or hygiene, has been awarded to Dr. Castaing for his works on ventilation. The prize of 2000 francs for an incandescent lamp of one-candle power, 100 volts, 1/20 ampere, has not been awarded, but an *encouragement* of 1000 francs has been given to MM. Javaux and Nysten, and a similar sum to M. Solignac. The prize of 2000 francs, for the best investigation on the comparative physical and chemical constitution of agricultural land in France, has also not been awarded, but 1500 francs have been granted to MM. Beuret and Brunet, and 500 francs to M. Waldmann. Grants of 1000 francs have been made to Prof. Zipcy and M. Jaffler as *encouragements* in connection with the prize of 2000 francs for pisciculture.

THE great sea-wave which accompanied the recent earthquake in Japan appears to have been even more destructive to life and property on the north-east coast than was at first reported. A dispatch received by the Japanese Legation, from Tōkyō, says:—"The loss of life and property caused by the tidal wave, which visited the north-east coast of Japan on June 15, is as follows, according to the official returns received up to the 22nd of that month. In the Prefecture of Aomori 346 lives lost, 840 houses washed away; in the Prefecture of Iwate, 23,309 lives lost, 5920 houses washed away; in the Prefecture of Miyagi, 3344 lives lost, 715 houses washed away. Besides the above, the number of persons injured is as follows: 213, 23,840, 1184 in the above Prefectures respectively."

DR. BROWN GOODE makes the following comparison in a Report of the U.S. National Museum, lately issued:—"There is not a department of the British Government to which a citizen has a right to apply for information upon a scientific question. This seems hard to believe, for I cannot think of any scientific subject regarding which a letter, if addressed to the scientific bureaus in Washington, would not receive a full and practical reply. It is estimated that not less than 20,000 such letters are received each year. The Smithsonian Institution and National Museum alone receive about 6000, and the proportion of these from the new States and Territories, which have not yet developed institutions of learning of their own, is the largest. An intelligent question from a farmer of the frontier receives as much attention as a communication from a Royal Academy of Sciences, and often takes more time for the preparation of the reply." It is little to the credit of British Governments that Dr. Goode's comparison should be so much to our disadvantage.

ACCORDING to the last report of the British Consul at the Piræus, a Pasteur Institute has been in existence in Athens for more than a year. During this period 201 cases have been treated, with only one death; in that case the patient had delayed submitting himself to treatment for fifteen days after

the infliction of the bite. The Institute was founded by Dr. Pampoukis, who studied for a time under M. Pasteur in Paris. He established the Institute at his own expense, but after a time the municipality and the Government granted him a small annual subvention. The Consul goes on to say: "It is practically impossible to over-estimate the value of such an establishment in the Levant, which is overrun with ownerless dogs. A muzzling order does exist in Attica, but it is not enforced, and the distribution of poisoned meat in the streets of Athens and the Piræus is apparently the only attempt made by the authorities to deal with an increasing amount of rabies."

IN view of the numerous applications of aluminium in the manufacture of water-bottles for military use, cooking utensils, and other articles where there is a necessity for lightness combined with resistance to corrosion, several researches on the behaviour of this metal towards liquids have been recently carried out. Mr. J. W. Richards, who has just published the latest contribution to this subject in the *Journal of the Franklin Institute*, has studied more especially how far the power of resisting the attack of corrosive liquids can be increased by alloying with small quantities of other metals. The general result of the experiments is to show that pure aluminium resists the action of alkaline solutions better than any of the alloys examined. This also holds true for solutions of nitric acid and of common salt; but an alloy containing 2 per cent. of titanium appears to be the best for liquids containing free hydrochloric acid. All the alloys tried offer great resistance to the action of acetic and carbonic acids.

MR. HENRY DEANE referred to the late Sir William Macleay's bequest for the endowment of a lectureship in bacteriology, in his presidential address to the Linnean Society of New South Wales, a copy of which has just reached us. It may be remembered that the Senate of the Sydney University decided to relinquish the bequest, and to return the money to the executors. This was done about a year ago, and the sum, amounting to £12,704, was afterwards paid into the Linnean Society of New South Wales. By the terms of the bequest, it has devolved upon the Council of the Society to invest the money, and use the interest to pay a competent bacteriologist, and maintain a suitable laboratory with appliances for bacteriological research. The result is that the Council has decided to appoint a bacteriologist at the close of the hot season 1896–97, provided that one can be engaged on what are practically the terms and emoluments offered to University demonstrators. A number of other subjects were passed in review by Mr. Deane in his address. His remarks upon forestry will perhaps do something towards checking the depletion of the forests of New South Wales.

AN important point dealt with by Mr. Deane in the address referred to in the foregoing note, is the origin of the vegetation of Australia. Prof. Ettingshausen's observations and conclusions are adversely criticised; and it is stated that at present the known facts seem to afford grounds for concluding: (1) That many, if not all, the typical Australian floral types originated in Australia or in some land connected with it, but now submerged. (2) That the assumption of the existence of a universal flora of mixed types at any epoch is unfounded. (3) That the fossil plant-remains of Tertiary age in Eastern Australia indicate a vegetation in all respects similar to that existing on the coast in the same latitude at the present day. To these Mr. Deane thinks may be added a fourth conclusion of less certain character, but of high probability, that the *Proteaceæ* represent a most ancient type which had their origin at a time when not only extensive areas of land existed in the southern hemisphere, but when some kind of connection, more or less lasting, existed between Australia and South Africa. Mr. Deane concluded his address with an account of the work of the Horn expedition to Central Australia.

MUCH attention has been paid in recent years to the prediction of the minimum night temperature, on account of its importance to agriculture, especially in spring-time, when late frosts are detrimental to delicate plants, and various important papers have been written upon the subject, *e.g.* by M. Kammermann, of the Geneva Observatory, and M. Lemström, of Helsingfors. Reference to the matter may also be found in some text-books of meteorology, where it is pointed out that if the dew-point is determined in the evening, it will rarely be found that the air temperature will fall much below that point during the night. In the current number of *Ciel et Terre*, M. Lancaster draws attention to the fact, which, if known, is not generally acknowledged, that as long ago as 1824 this relation between the night minimum and the temperature of the dew-point was indicated by Dr. A. Anderson, in a note entitled "On the influence of the hygrometric state of the atmosphere upon the minimum temperature of the night," printed in vol. xi. pp. 161–9 of the *Edinburgh Philosophical Journal*. The same author also refers incidentally to the subject in a short note "On the Dew-point," presented to the British Association in 1840. As M. Lancaster says, this is one of many instances presented by the history of science, of problems being studied, which have been long since solved.
